(Received 6 March 1974; revised 21 May 1974)

INTRODUCTION

The existence of yeasts capable of utilizing methanol as the only source of carbon and energy for growth has been discovered comparatively recently by studying new isolates and screening culture collections (Ogata, Nishikawa & Ohsugi, 1969; Asthana, Humphrey & Moritz, 1971; Sahm & Wagner, 1972; Oki, Kouno, Kitai & Ozaki, 1972; Hazeu, de Bruyn & Bos, 1972; Levine & Cooney, 1973). The yeasts belonged to the genera Kloechera, Torulopsis, Candida, Pichia and Hansenula.

We have isolated 36 different strains of Candida boidinii and Pichia pinus from more than 600 enrichment cultures prepared during a survey of conditions leading to the enrichment of methanol-assimilating yeasts.

METHODS

Media. These contained (per litre deionized water): (NH₄)₂SO₄, 0·5 g; MgSO₄·7H₂O, 0·2 g; KH₂PO₄, 3·0 g, and 0·2 ml of a trace element solution (Vishniac & Santer, 1957). The preferred enrichment medium contained in addition (per litre deionized water): vitamin mixture (Ogata, Nishikawa, Ohsugi & Tochikura, 1970), 10 ml; sodium penicillin G (Mycofarm, Delft, The Netherlands), 10⁶ units; D-cycloserine (Sigma), 600 mg; and methanol, 5 ml. The pH was adjusted to 4·5 with NaOH. The medium was used without sterilization. The utilization of methanol by the isolated yeast strains was studied in the above solution at pH 5·5 in the absence of the antibiotics. In that case the vitamin mixture and methanol were filter-sterilized and added to the mineral medium which had been sterilized at 15 lb/in² for 15 min and cooled.

These organisms were maintained on 1% Difco Malt agar and subcultured twice a year. Slopes were incubated overnight at 28 °C (except for H. polymorpha which was incubated at 37 °C) and then stored at 4 °C.

Enrichment and isolation. Conical flasks (100 ml) containing 30 ml of enrichment medium were inoculated with approximately 1 g of samples taken from soil, rotten wood, leaves, flowers and fruit. The flasks were put on a shaker (Model G25, New Brunswick Scientific Co.) at 28 or 37 °C. They were examined microscopically at 2-day intervals for 3 weeks. In positive enrichments growth of yeasts generally started after 5 to 8 days and after 10 days the cultures were transferred to another flask containing the enrichment medium. Growth
in the second flask was much faster, and 3 days after the transfer samples of the culture were plated on a modified enrichment medium without antibiotics, at pH 5.5, containing 20 g Difco Bacto-agar/l. Pure cultures of the yeasts were obtained by means of conventional techniques.

Criteria for methanol utilization. A 100 ml conical flask, containing 30 ml of the mineral salts medium + vitamins and supplemented with 0.2 % (w/v) glycerol, was inoculated from a 48 h old slope and incubated on a shaker at 28 °C (37 °C for H. polymorpha). When growth was apparent, 0.2 ml of the culture was transferred to another flask containing 30 ml of the modified enrichment medium at pH 5.5, containing 0.2 % (w/v) glycerol and 0.5 % (v/v) methanol. After 48 h of incubation, 0.2 ml of the culture was transferred to a similar solution containing only methanol as the carbon source. When after five subcultures in the latter medium growth was visible within 72 h, the yeast under study was considered to assimilate methanol.

Identification of the isolated yeasts. This was done by standard methods (Lodder, 1970).

RESULTS AND DISCUSSION

Preliminary work showed that at pH 4.5 penicillin G and D-cycloserine virtually prevented bacterial growth in the enrichment cultures. Yeasts were obtained from 15 to 25 % of these.

Of 36 strains eventually isolated in pure culture, 26 were identified as P. pinus, and 10 as C. boidinii. Only C. boidinii was isolated when (NH₄)₂SO₄ was replaced by 0.065 % (w/v) KNO₃ as the nitrogen source. Pichia pinus is unable to use nitrate as a nitrogen source for growth (Lodder, 1970). The enrichments were particularly successful when soil, rich in organic matter, from a tropical greenhouse was used as the inoculum. It is notable that when the incubation temperature during the enrichments was 37 °C no yeasts were isolated. A thermo-tolerant Hansenula strain has been isolated, however, by Levine & Cooney (1973) and H. polymorpha CBS4732 utilized methanol at 37 °C in our experiments. The optimal conditions for the isolation of methanol-assimilating yeasts are summarized in Table 1.

A number of yeast species taxonomically related to our isolates were obtained from the Delft collection. From the genera Pichia and Hansenula all the available type species were tested, whereas from the genus Candida only those species resembling C. boidinii were considered. By using the criteria outlined above the following species were found to grow with methanol as the sole source of carbon and energy: H. capsulata, H. nonfermentans, H. polymorpha, H. wickerhamii, H. hircii, P. pastoris, P. pinus, P. trehalophila and C. boidinii. In contrast to the results reported by Hazeu et al. (1972), H. glycozyma and H. minuta

* Biotin and thiamin are especially important.
failed to utilize methanol. This discrepancy may be due to the use of different criteria for methanol utilization.

All methanol-assimilating yeasts tested so far are unable to grow in batch or continuous culture with the following one-carbon compounds: methane, methylamine, formaldehyde and formate. The results obtained so far indicate that the utilization of organic C1 compounds is not widespread among yeasts and is less common than among procaryotic organisms (Quayle, 1972).

We are indebted to Dr N. J. W. Kreger van Rij for the identification of our isolates and for her most valuable suggestions for the screening of yeast strains. One of us (J.P.v.D.) was supported by a grant from Shell Research Ltd, Sittingbourne, Kent.
