An Attempt to Identify the Intestinal Receptor for the K88 Adhesin by Means of a Haemagglutination Inhibition Test using Glycoproteins and Fractions from Sow Colostrum

By R. A. GIBBONS, G. W. JONES AND R. SELLWOOD

Agricultural Research Council, Institute for Research on Animal Diseases, Compton, Newbury RG16 ONN, Berkshire

(Received 17 June 1974; revised 9 September 1974)

SUMMARY

The K88 antigen of *Escherichia coli* specifically adheres to the piglet intestinal cell; a solution of this antigen agglutinates guinea-pig red cells at 4 °C. The latter reaction was used as a model of the former, using inhibition of haemagglutination as an index of specific combination with the K88 adhesin. Inhibition was found with mucous glycoproteins and chemical modification of their heterosaccharide residues by mild acid hydrolysis, periodate oxidation or the Smith degradation procedure suggested that the terminal β-D-galactosyl structure in a heterosaccharide side-chain of a glycoprotein might combine specifically with the K88 adhesin and inhibit haemagglutination. One serum glycoprotein (fetuin), after exposure of its subterminal β-D-galactosyl residue, also inhibited haemagglutination, but high inhibitory activity was exhibited by some submaxillary glycoproteins in which this structure was absent or not prominent. It was concluded that in some cases inhibition of haemagglutination by glycoprotein was non-specific. No inhibition was found using glycosaminoglycans, glycogen or any simple sugar or glycoside. Sow colostrum was inhibitory but this was associated mainly with its γ-globulin fraction. Some inhibitory activity was traced to a colostral glycopeptide fraction of low molecular weight but the smaller colostral oligosaccharides were not inhibitory; the composition of these components in sow colostrum is reported.

INTRODUCTION

Most serotypes of *Escherichia coli* that cause diarrhoea in neonatal piglets produce a K antigen designated K88 (Sojka, 1971). Arbuckle (1970) showed that several strains belonging to K88-positive serotypes adhered to the mucosa of the piglet small intestine and Smith & Linggood (1972) concluded that the ability of a strain to proliferate in the anterior small intestine was enhanced after the strain had acquired the capacity to produce K88 antigen. Jones & Rutter (1972) demonstrated that the synthesis of K88 antigen by *E. coli* in the intestine of the piglet conferred adhesive properties on the bacterial cell that enabled K88-positive *E. coli* to attach to and colonize the mucosa; its K88-negative mutant did not adhere and was virtually avirulent to conventional piglets. Thus an essential element in the pathogenic character of these bacteria for the neonatal piglet appears to be their ability (conferred by the presence of K88 antigen) to adhere to the mucosal surface of the small intestine and subsequently proliferate in this favourable location.

A solution of K88 antigen obtainable from K88-positive *E. coli* agglutinates guinea-pig red cells at 4 °C (Jones, 1972; Jones & Rutter, 1974). The haemagglutinin cannot be sepa-
rated from the K88 antigen. The haemagglutination reaction (HA), which is much easier to study than the adhesion of bacteria to the intestinal cell, ought to provide a convenient test system for the study of the important and specific interaction between host and pathogen. In particular, the inhibition of the haemagglutination reaction by substances of known structure — one of the techniques which has been so successful in elucidating the chemical structure of the human ABO and Lewis blood group receptors (Watkins & Morgan, 1962a, b; Watkins, 1972) — could be used to reveal the chemical structural requirements for combination with K88, and by inference the structure of the receptor for K88 present in the intestinal cell wall of the susceptible piglet. However, K88-positive E. coli adhere to the porcine gut cell at 37 °C. Preliminary work has shown that this interaction occurs in vitro between bacteria and suspensions of pig intestinal brush borders (R. Sellwood, unpublished) and, unlike the HA, it is insensitive to temperature between 4 and 37 °C. Since HA only occurs at low temperatures the 'fit' for the guinea-pig red cell receptor and the K88 antigen is probably not as good as it is for the natural receptor.

Jones (1972) found that the contents of the small intestine of the germ-free colostrum-deprived piglet contained an HA inhibitor which had the properties of a glycoprotein or polysaccharide (heat resistance, stability to proteolytic enzymes, insolubility in chloroform/methanol, and susceptibility to oxidation with periodate). Thus it seems reasonable to suppose that the structure in the cell membrane (of the piglet intestinal cell and of the guinea-pig red cell) with which K88 specifically combines is a glycoprotein; also that the determinant structure is likely to be at or near the terminal non-reducing ends of the heterosaccharide residue(s). Accordingly, the ability of selected glycoproteins to inhibit the HA reaction has been determined. The structures of the heterosaccharide residues of most of these glycoproteins are known and can be modified chemically in known, specific ways, giving a wide variety of structures whose inhibitory titres can be compared.

Included in these glycoproteins were two samples isolated from pig small intestine, which probably represent purified samples of the inhibitor which Jones (1972) originally described. Pigs have three genetically determined mucus glycoprotein structures, termed H, AH and In (Chadwick, Smith, Annison & Morgan, 1949; Aminoff, Morrow & Zarafonetis, 1964); the relevant structures (similar to but not identical with those of the human blood-group substances) are given by Slomiany & Meyer (1973) and Baig & Aminoff (1973). The In phenotype has not been detected in the intestinal glycoprotein in this laboratory, but both H and AH samples have been examined separately. A number of simple sugars, some of their glycosides, two glycosaminoglycans and one polysaccharide have also been tested for HA inhibition.

The HA inhibition test could help to clarify another important aspect of the pathogenesis of neonatal diarrhoea in piglets. Although the colostral immunoglobulins are protective against the disease in the piglet (Kohler & Bohl, 1966; Miniats, Mitchell & Barnum, 1970; Wilson, Gyles & Svendsen, 1971; Smith, 1972; Rutter & Jones, 1973; Brandenburg & Wilson, 1973), in other species the immunoglobulin fraction seems to be less important (Kenny, Weinert & Gray, 1974) and substances in colostrum other than immunoglobulins may have an additional protective effect in the neonatal gut. Oligosaccharides in human colostrum have the same sugar sequence as the epithelial glycoprotein heterosaccharide residues and the surface glycolipid antigens of some cells (Hakomori & Jeanloz, 1970; Huang, 1971; Kobata & Ginsberg, 1972a, b), and milk oligosaccharides appear important in the protection of the human baby (Schönfeld, 1927; Gyorgy, Norris & Rose, 1954; Grimmond-prez, 1971). There is the possibility, therefore, that non-lactose colostral saccharides react with the K88 adhesin and thus reduce the adhesive ability of K88-positive E. coli, rendering
them less able to colonize the small intestine. Milk oligosaccharides are to be found in every species of mammal examined, in marsupials and even in monotremes (Messer & Kerry, 1973). While the human oligosaccharides have been well investigated (Kuhn & Gauhe, 1962a, b, 1965; Kobata & Ginsberg, 1972a, b), those from other mammals are less well characterized. Consequently we have carried out a preliminary chemical characterization of sow colostrum paying particular attention to the oligosaccharide fraction and the ability of its components to inhibit K88-mediated HA.

METHODS

**Haemagglutination-reaction inhibition test.** Four to eight haemagglutinating doses of K88 haemagglutinin in 25 µl vols. were incubated on ice for 15 min with equal volumes of serial twofold dilutions of test substance. Guinea-pig red cell suspension (25 µl vols.; 3%, v/v) was then added and the mixture incubated at 4 °C for 2 h (Jones, 1972; Jones & Rutter, 1974). The HA inhibition titre was taken as the highest dilution of test material that inhibited haemagglutination.

**Precipitin reaction.** This was in the immunodiffusion medium of Jones & Rutter (1972) with whole sow colostrum and their partially purified K88 antigen. The density of the precipitin lines was assessed by eye after 7 days at 4 °C.

**Glycoproteins.** Submaxillary glycoproteins from sheep (OSM), pig (PSM) and cattle (BSM) were prepared by the method of Heimer & Meyer (1956). PSM was also prepared as described by Gibbons (1963). Human blood-group substances were prepared from ovarian cyst mucin (Gibbons, Morgan & Gibbons, 1955). Intestinal glycoprotein from the pig was isolated as described by Gibbons, Dixon & Pocock (1973). Bovine cervical mucus glycoprotein was the sample isolated from the oestrous secretion by Gibbons & Sellwood (1973). Fetuin and α1 acid glycoprotein were commercial samples (Koch-Light Laboratories Ltd, Colnbrook, Buckinghamshire).

**Glycosaminoglycans.** Heparin was from BDH, and hyaluronic and chondroitin sulphuric acids from Sigma.

**Glycogen.** This was a commercial sample from Sigma.

**Chemical modification of the glycoproteins.** (i) By mild acid hydrolysis. The submaxillary gland glycoproteins (0.25%) were hydrolysed in sulphuric acid (0.1 M) for 2 h at 80 °C to remove the major portion of the neuraminic acid and also, where present, much of the fucose. Fetuin was hydrolysed for 1 h only; the neuraminic acid in this glycoprotein is more readily removed.

(ii) By alkali-borohydride treatment (Bertolini & Pigman, 1970). The reaction mixture was then neutralized, freeze-dried and passed down a column (1 x 100 cm) of Sephadex G50 (Pharmacia) at room temperature. The fractions containing carbohydrate were passed down a column (1.5 x 60 cm) of Biogel P2 (Biorad Laboratories Ltd, Bromley, Kent). Chloroform-saturated water was used as the eluant.

(iii) Periodate oxidation. To 7 ml of 0.1 M-NaIO4 in sodium acetate-acetic acid buffer (1 M, pH 3.5) were added 50 mg of the glycoprotein dissolved in 28 ml water. After 3 h in the dark at 4 °C, 0.35 ml of 2% (v/v) aqueous ethylene glycol was added. The solution was dialysed against running distilled water for 24 h at 4 °C; a sample was withdrawn and freeze-dried to ascertain the concentration of the oxidized glycoprotein.

(iv) Periodate oxidation/borohydride reduction and (v) Smith degradation (Smith & Unrau, 1959). The periodate oxidation stage was carried out as already described except that the oxidation was allowed to go to completion (17 h). The volume of indiffusible material was adjusted to 50 ml and solid sodium borohydride (0.33 g) added at 4 °C with stirring.
Haemagglutination inhibition by K88 adhesin

whilst 2 m-HCl was added by a pH-stat (Metrohm Ltd, CH-9100, Herisau, Switzerland) to maintain the pH at 8·0. Sodium borohydride solution (0·2 M in 50 %, v/v, aqueous ethanol containing 0·01 M-NaOH) was added at a rate of 5 ml/h continuously for 18 h at 4 °C with pH-stat control to pH 8. At this stage one of two courses was followed. For method (iv) (borohydride-reduced material), the pH was brought to 5·0. For (v), where it was desired to cleave the oligosaccharide residues at the points of periodate attack using a modified Smith degradation, the solution was adjusted to pH 1·2 and held at 65 °C for 2·5 h. Subsequently, for both procedures (iv) and (v), the reaction mixture was freeze-dried, dissolved in a small quantity of water, dialysed at 4 °C to zero ionic strength, and freeze-dried.

The scale of the reactions was varied as circumstances required, but the proportions were maintained as closely as possible to those given above.

Sow colostrum. Colostrum was collected manually from sows up to 6 h post partum and stored at -20 °C; all animals were from the Institute's minimal disease herd. When required, quantities of about 200 ml were thawed and centrifuged at approx. 40000 g for 4 h to separate the cream and the casein from the colostral whey. Portions of whey (25 ml) were fractionated at 4 °C on a column (5 x 100 cm) of Sephadex G200 eluting with 0·05 M-sodium acetate–acetic acid buffer, pH 6·5, containing 0·1 % sodium azide. The eluate was monitored at 280 nm and appropriate fractions were pooled. Each fraction was examined by polyacrylamide gel electrophoresis. The retarded fractions (E and F, see later), richer in carbohydrate material, were refractionated on Sephadex G25 columns (2 x 100 cm) eluting with chloroform-saturated water. Fractions from this column were further purified by fractionation on Biogel P2. Column eluates were in these latter two cases monitored for protein (extinction at 230 nm), sugars (Yemm & Willis, 1954) and neuraminic acid (Svennerholm, 1957).

The yield of oligosaccharide from colostral whey could be improved by using the method of Öhman & Hygstedt (1968), although the protein fraction is lost. The carbohydrate-rich aqueous layer was concentrated under reduced pressure and fractionated as above, substituting Biogel P4 for P2.

Paper chromatography. Descending chromatograms (Whatman No. 4) irrigated with the single-phase system ethyl acetate–acetic acid–pyridine–water (Fischer & Nebel, 1955) were run. Spots were visualized using silver nitrate in ethanolic potassium hydroxide (Heimer, 1957), or periodatopermanganate (Wolfrom & Miller, 1956).

RESULTS

Haemagglutination-reaction inhibition tests with glycoproteins, glycosaminoglycans and various carbohydrates

The inhibition of haemagglutination by all the epithelial glycoproteins examined (Table 1) confirmed the earlier observation of Jones (1972). The structurally different serum glycoproteins and the markedly different glycosaminoglycans were not inhibitory. However, the lack of inhibition by monosaccharides commonly found as constituent parts of mammalian glycoproteins, or by their α- and β-methyl glycosides, suggests that the inhibitor site is probably larger than a single sugar residue.

Haemagglutination-reaction inhibition tests with chemically modified glycoproteins. Human A and H substances are the best characterized of the more complex glycoproteins, to which pig intestinal glycoprotein is probably similar (Table 2). Periodate oxidation of human A and H substances, which destroys the terminal sugar residues responsible for serological activity, also destroyed their inhibitory activity. The subsequent reduction and

* The following sugars and methyl glycosides were all non-inhibitory at 5 mg/ml: D-arabinose, D-xylene, D-ribose (BDH), D-galactose (Sigma), and its α and β methyl glycosides, D-mannose (BDH), L-rhamnose, L-fucose and its α methyl glycoside, N-acetyl- or N-glycollyl neuraminic acid (Sigma), 2-deoxy-2-acetamido-D-glucose or D-galactose (Koch Light) and the α and β methyl glycosides of both the N-acetylhexosamines, lactose, maltose, melibiose, trehalose, sucrose, cellobiose, raffinose and glycogen (BDH).

Table 2. Chemical analysis of glycoproteins

Hexosamine is expressed as the free base, and neuraminic acid as the N-acetyl compound except in the case of porcine submaxillary glycoprotein where an appropriate correction factor (Gibbons, 1963), is used to convert to the N-glycollyl derivative actually present. Analytical methods were as follows. Hexose: Yemm & Willis (1954), using galactose as standard. Hexosamine: Rondle & Morgan (1955), after 16 h at 100 °C in 0.5 N-HCl. Neuraminic acid: Warren (1959), after 2 h at 80 °C in 0.01 N-H₂SO₄. Fucose: Gibbons (1955).

removal of the terminal polyhydric alcohols resulted in a re-expression of some HA inhibitory activity (Table 3) although blood group activity remained lost. The results of chemical modification of the structurally simpler submaxillary gland glycoproteins (Tables 2 and 3) are difficult to interpret, one reason being that no treatment completely eliminated HA inhibition unless the molecule was extensively fragmented. Degradation of BSM and PSM by alkali in the presence of borohydride generates a number of small oligosaccharides, usually terminating in N-acetylgalactitol (McGuire, 1970). A fraction was isolated in poor yield

(7 mg from 115 mg of PSM) which was excluded on Sephadex G50, had a high extinction at 230 nm, but only traces of neuraminic acid or sugar. This is the (somewhat degraded) peptide portion of the glycoprotein and neither it nor the separated oligosaccharide fraction was inhibitory.

Haemagglutination-reaction inhibitory activity of sow colostrum and colostral fractions

Inhibitory activity was present in all 12 samples of colostrum tested. The inhibitory titre was not correlated with either parity of the sow or the presence of precipitins against the K88 preparation. Indeed, the most active sample lacked detectable precipitins.

Seven fractions, designated A to G, were normally isolated from colostrum on a Sephadex G200 column (Fig. 1). The first four were probably analogous to those reported by Kessler & Brew (1970). Three further retarded fractions which were anthrone positive were eluted with and after the β-lactoglobulin peak. The peak denoted A (Fig. 1) was characterized as, in the main, porcine γ-globulin by electrophoresis (Davis, 1964) and by immunodiffusion (Ouchterlony, 1964) against specific anti-porcine γ-globulin (kindly supplied by Dr J. M. Rutter, Compton).

In Fig. 2 are shown typical disc electrophoretic patterns for fractions A to F from the first gel-filtration fractionation of crude colostral whey. Porcine serum is also shown. The results are consistent with those of Karlsson (1966). Only traces of β-lactoglobulin were found in the final fraction. In addition to inhibitory activity in fraction A, which is probably associated
with immune globulin, there was weak activity in fractions E and F (Table 4). Fraction G was almost pure lactose, although both E and F were contaminated with this sugar. These two fractions could be purified on Sephadex G25 and G10 columns to yield a nearly pure fraction of neuramin-lactose (Fig. 3). Its identity was confirmed by (i) hydrolysis, identification and quantitation of glucose and galactose on amberlite columns (Kessler, 1967); (ii) comparison of its elution volume, without prior hydrolysis, on the same column with that of authentic neuramin-lactose (Sigma) [the latter contained both the 2 → 3 and 2 → 6 neuramin-

lactose (Kuhn & Gauhe, 1965) whereas our sample was almost entirely the 2 → 3 compound; and (iii) by paper chromatography both of the trisaccharide and its hydrolysis products. Neuramin-lactose was not inhibitory in the HA reaction.

Deproteinized whey (from which all higher molecular weight materials, including immune globulins, had been removed) was fractionated on Biogel P4 (Fig. 3 and Table 5). Residual HA activity, not assignable to immune globulin, was found to be concentrated in fractions 1 and 2 which may be identified from their u.v. extinction and chemical analysis as glycopeptides. The third fraction is probably a mixture of tetra and higher oligosaccharides; it contained appreciable hexosamine, and the glucosamine:galactosamine ratio (Lee, Scocca & Muir, 1969) was 2·6:1. This fraction was an almost negligible proportion of the whole, however, and it too had low HA inhibitory activity.

* P4/7 was isolated in insufficient yield for analysis. Only fraction P4/8 had an appreciable extinction at 254 nm.

The remaining fractions were not pure, although some were subsequently purified by further column chromatography: in order of elution, they proved to be neuramin-lactose, lactose, glucose, an unidentified compound, and probably a nucleotide (Table 5).

DISCUSSION

Mucus glycoprotein from the pig intestine was inhibitory in the HA test, which implies that this substance contains the same structure as the intestinal receptor; the latter is known to be present on the brush border of the pig gut cell (R. Sellwood, unpublished). The intestinal mucus might therefore be expected to function as an inhibitor in vivo. To account for the fact that it evidently does not, the following mechanism is tentatively proposed. After adhering to the mucus gel layer overlying the intestinal epithelium, the organism can lyse the protective layer locally by virtue of a membrane-located protease which it possesses (Regnier & Thang, 1973). This would afford a passage for the organism through the mucus layer to the susceptible cell, to which the K88 antigen would then allow it to adhere. While this mechanism is hypothetical, it is based on a similar enzymic arrangement which allows spermatozoa to penetrate the mucus of the mammalian cervix (Gaddum & Blandau, 1970; Blandau, 1973). Once adherence is established the bacterium is in a more favourable environment than that of the lumen of the gut; it can now proliferate and cause (if it also produces enterotoxins) disease.

The unsubstituted β-D-galactosyl residue appears to be an important feature of the structural chemical requirements of the binding site of the K88 adhesin. Removal of the terminal non-reducing fucosyl and N-acetyl galactosaminoyl residue from A substance – which would leave a terminal β-D-galactosyl residue – somewhat increases the inhibitory activity. The same procedure, however, applied to H substance will remove the terminal α-L-fucosyl residue, as the terminal sugar, a β-D-N-acetylglucosaminoyl residue (Morgan & Watkins, 1969). This reduces the HA inhibition. The further observation that removal of the terminal neuraminic acid from fetuin makes this glycoprotein inhibitory would tend to confirm the importance of β-D-galactosyl since the modification exposes an unsubstituted β-D-galactosyl residue. This linkage is also present, though not predominant, in pig submaxillary glycoprotein (Carlson, 1968), the most potent inhibitor found. It is probably present also in pig intestinal glycoprotein in both the H and AH active phenotypes. On the other hand, it cannot be asserted that there is any correlation between the amount of terminal β-D-galactosyl residue present and the inhibition titres. Moreover, sheep submaxillary glycoprotein, a very active inhibitor, is almost devoid of galactose (Table 2).
Further, the sample of fetuin from which the terminal neuraminic acid residue had been cleaved suffered some reduction in its inhibitory activity when treated to remove the sub-terminal galactose residue, but the activity was not abolished.

All the most potent inhibitors, the submaxillary glycoproteins, are characterized by a predominant terminal neuraminic acid residue. The results do not indicate that this residue is involved in specific combination with K88. The removal of > 80% of the terminal neuraminic acid caused only a two- to three-fold decrease in activity. As already stated, fetuin causes inhibition only after neuraminic acid has been removed, which suggests that in this substance neuraminic acid actually blocks the inhibitory site.

Very approximately, the haemagglutination inhibition titre of the submaxillary gland glycoproteins decreases at the same rate as carbohydrate is removed (Tables 2 and 3). PSM, the most inhibitory glycoprotein, differs from OSM and BSM in that the terminal residue is N-glycolloyl- rather than N-acetylneuraminic acid. Bovine cervical glycoprotein which also possesses N-glycolloylneuraminic acid was a relatively weak inhibitor. The substitution of glycolloyl for acetyl in the terminal neuraminic acid is unlikely to be a determinant factor in the requirements of the K88 combining site.

Considering the non-immunoglobulin material in sow colostrum, our experiments have failed to demonstrate that the non-lactose oligosaccharides inhibit K88-mediated HA to any great extent. Our new data on the composition of pig colostrum show that, like the cow, the major non-lactose sugar is neuramin-lactose (Table 5) and the higher oligosaccharides are present in rather minor amounts. Fucose-containing oligosaccharides appear to be almost absent. Evidence for the occurrence of both small nucleotides, as in cow colostrum (Kieffer, Solms & Egli, 1964) and of glycopeptide as in man (Vignati et al. 1968; Nichols & Bezkorovainy, 1973) and cow (Kuhn & Ekong, 1963) was also found; this latter fraction contained most of the rather weak inhibitory activity of colostrum referable to the non-immunoglobulin material (Table 4). This ability to combine with K88, although weak, could influence the initial stages of colonization of the intestine by small numbers of enteropathogenic E. coli when even a slight reduction in, or interference with these molecular interactions may be sufficient to tip the balance in favour of the other protective mechanisms which undoubtedly function in the gut.

Our results are unfortunately less clear-cut than those which led to the identification of the influenza virus receptor by a similar approach (Gottschalk, Belyavin & Biddle, 1972). There are a number of factors bearing on this point which should be considered. The virus receptor is an N-acetylenuraminidyl residue, which is invariably terminal in a heterosaccharide side-chain, whereas the β-D-galactosyl residue normally is not. As a result of 'microheterogeneity' (Montgomery, 1972), there are always some incomplete sugar chains present in a complex glycoprotein, on some of which the relevant terminal β-D-galactosyl residue will be present. This is well shown in the case of the blood-group substance heterosaccharides (Rovis et al. 1973). We thus have a situation where the stepwise removal of an active terminal residue from one heterosaccharide side chain occurs concomitantly with the exposure of a sub-terminal β-D-galactosyl residue in another side chain; comparison of Tables 1 and 3 shows many instances where the selective removal of a terminal saccharide from a glycoprotein enhances or reduces activity, but few in which activity is completely abolished. On the other hand, the complete inactivity of the heterosaccharide side chains from pig submaxillary mucin cleaved by a technique which does not change the sugar chain structure except in the region where it originally adjoined the polypeptide moiety, suggests that a minimum molecular size is required and also, possibly, that other more stringent stereochemical requirements exist.
Finally, the lack of a β-D-galactosyl structure in one of the inhibitory glycoproteins studied probably indicates that there is a degree of non-specific interaction between K88 antigen and the complex, high molecular weight glycoproteins which are found in mucus secretions. The fact that this was detected may be a reflection of the relative weakness of the HA reaction compared with the reaction between K88 and the intestinal cell.

The human A and H substances and the methyl glycosides listed in Table 1 were the kind gift of Professor W. M. Watkins.
