SUMMARY

Lipopolysaccharides, extracted by phenol–water from five strains of Neisseria gonorrhoeae, were purified by treatment with ribonuclease followed by multiple washes. These preparations were fatal to mice when administered in submicrogram amounts with actinomycin D, the LD₅₀ values varying from 4 to 16 µg/kg. Analyses showed that all preparations contained glucose, galactose, glucosamine, heptose, 2-keto-3-deoxyoctonic acid and phosphate. All the lipopolysaccharides contained the same fatty acids, namely β-OH-10:0, β-OH-12:0, β-OH-14:0, 12:0, 14:0, 16:0, 16:1, 18:0 and 18:1. We were unable to detect significant differences between the lipopolysaccharides of virulent and avirulent gonococci or between penicillin-sensitive and resistant strains. Gonococcal lipopolysaccharides appeared to lack O-antigen side chains.

INTRODUCTION

Despite extensive investigations on the endotoxic lipopolysaccharides (LPS) of the Enterobacteriaceae, there have been relatively few studies on the Neisseriaceae. Neisseria differ from other Gram-negative bacteria in their extreme sensitivity to penicillins. In Pseudomonas aeruginosa differing susceptibilities to penicillins have been correlated with LPS structure (Meadow, 1972). Perhaps the penicillin sensitivity of Neisseria is a reflection of a different type of LPS structure.

Lipopolysaccharide was the target antigen involved in the killing of Neisseria gonorrhoeae (gonococci) by antibody and complement (Glynn & Ward, 1970). These workers suggested that LPS might be used in the serotyping of gonococci. The O-antigen chains of LPS are responsible for serological specificity in Salmonella and are important in the serological diagnosis of enteric fever. There have been no reports of O-antigen chains on gonococcal LPS (Tauber & Garson, 1959; Maeland & Kristoffersen, 1971). Nevertheless, Watt, Ward & Glynn (1971) reported the use of latex particles coated with LPS as an antigen for the serological diagnosis of gonorrhoea. In order to pursue our investigations of the biological significance of gonococcal LPS, we have prepared, purified and analysed LPS extracted from both freshly isolated and old laboratory strains of gonococci.

METHODS

Bacterial cultures. We used Neisseria gonorrhoeae colony type 1 strains P9 and F62, colony type 4 strains G2, G4 and G50 (Kellogg et al. 1963), and strain A24 which was resistant to 0.5 µg penicillin/ml.

Cultivation and harvesting. Gonococci stored in liquid nitrogen (Ward & Watt, 1971) served as inocula for starter cultures on GC agar (Difco) grown overnight in a moist atmosphere containing 5% CO₂. Organisms from 50 plates were harvested aseptically by
An A. STEAD, J. S. MAIN, M. E. WARD AND P. J. WATT

suspension in 100 ml 1 % (w/v) proteose peptone No. 3 broth (Difco). Organisms were
grown in 5 l volumes in a stirred jar fermenter (New Brunswick Scientific) in medium con-
taining (per litre): proteose peptone, 15 g; NaCl, 5 g; K$_2$HPO$_4$, 4 g; dextrose, 4 g; glutama-
ine, 50 mg; Fe(NO)$_3$, 10 mg; co-carboxylase, 0.2 mg. Polypropylene glycol 2000 (Shell
Chemicals), 0.1 ml/l, was used as antifoam. Bacteria were grown at 37 °C and 15 % O$_2$
saturation, with stirring (300 rev./min), until the extinction of a 1:5 (v/v) dilution of the
culture had reached 0.25, which took between 5 h for old laboratory strains to 8 h for freshly
isolated ones. Then the culture was harvested at 22000 g using a continuous action rotor
with a flow rate of 120 ml/min.

**Extraction of LPS.** Whole cells from strains P9, F62, G2, G4 and G50 were treated with
45 % (w/v) aqueous phenol (Westphal & Jann, 1965). The aqueous phases were centrifuged
at 20000 g to remove contaminating peptidoglycan and dialysed for 3 days against tap
water. Crude LPS was precipitated by 3 vol. of acetone (4 °C) in the presence of a trace of
MgCl$_2$. After 2 h at 4 °C the precipitate was spun down at 20000 g, redissolved in water and
dialysed for 24 h against distilled water. The non-diffusible material was treated with 1 mg
pancreatic ribonuclease (Koch-Light)/ml at pH 7.2 for 16 h and centrifuged at 100000 g for
3 h to sediment the LPS. The pellet was washed 3 times with 0.1 % (w/v) NaCl and twice with
distilled water. Loosely-bound lipids were removed by stirring the LPS for 2 h at room
temperature (approx. 18 °C) with chloroform–methanol (2:1, v/v; 100 ml/20 mg LPS) as

LPS was isolated from strains P9 and A24 by washing with chloroform–methanol (2:1, v/v; 100 ml/g bacteria) followed by the use of hydrolytic enzymes as described by Lehrer & Nowotny (1972). Lysozyme (from egg white), protease type VII (bacterial), alkaline
phosphatase (EC. 3.1.3.1; from Escherichia coli) and phosphodiesterase type II (from Crotalus adamanteus venom) were all purchased from Sigma.

**Removal of lipid A.** To cleave LPS into its lipid A and polysaccharide moieties, 50 mg
samples were hydrolysed with 1 % (w/v) acetic acid (5 ml) at 100 °C for 1.5 h under N$_2$ and
chloroform-soluble and water-soluble products were separated as described by Wilkinson
et al. (1973).

**Qualitative analysis.** The LPS preparations were hydrolysed in 2 M-HCl at 100 °C for 3 h
under N$_2$ for neutral sugar analysis, and in 6 M-HCl at 105 °C for 4 h under N$_2$ for amino
compounds. All hydrolysates were dried repeatedly in vacuo over P$_2$O$_5$ and KOH.

Neutral sugars were examined by descending paper chromatography on Whatman No. 1
reagent (Morgan & Elson, 1934) and ninhydrin (Consden & Gordon, 1948). Amino acids
were similarly examined by paper chromatography in solvent system propan-1-ol–ammonia–
water (6:3:1, by vol.) and were detected by ninhydrin reagent (Consden & Gordon, 1948).

**Quantitative analysis.** Phosphorus was determined by the method of Chen, Toribara &
Warner (1956) and carbohydrate by the phenol–sulphuric acid reaction (Dubois et al. 1956).
Heptose was measured as glucosheptose using the method of Osborn (1963), and 2-keto-3-deoxyoctonic acid (KDO) determined by the thiobarbituric acid reaction (Waravdekar & Saslaw, 1959) and the semicarbazide reaction (MacGee & Doudoroff, 1954). Protein was
measured by the method of Lowry et al. (1951). Fatty acid esters were estimated by the
method of Snyder & Stephens (1959), using tripalmitin for calibration. Glucosamine was
measured as glucosamine-HCl (Kraan & Muir, 1967), and N-acetylglucosamine by the
Lipopolysaccharides of Neisseria gonorrhoeae

Glucostat and Galactostat (Worthington Biochemical Corp., Freehold, New Jersey, U.S.A.) were used for quantitative analysis of glucose and galactose. Glucose and galactose ratios were also determined by preparation of alditol acetates (Shaw & Moss, 1969) analysed by g.l.c. on a Pye series 104 gas chromatograph using a flame ionization detector and a glass column (6 mm x 1.5 m) containing 3 % (w/w) ECNSS-M (Pye Unicam Ltd) on acid-washed diatomite ‘c’, operating at 190 °C. Nitrogen was used as carrier gas at a flow rate of 45 ml/min.

Identification of fatty acids. Methyl esters of fatty acids in loosely bound lipids were prepared by treatment with 0.2 M-NaOMe (Marinetti, 1962). Fatty acids were released from samples of lipid A by hydrolysis with 6.1 M-HCl at 105 °C for 4 h and were esterified using ethereal diazomethane. Fatty acids were examined by g.l.c. on a glass column (6 mm x 1.5 m) containing 15 % (w/w) polyethyleneglycol succinate on acid-washed diatomite ‘c’ at 175 °C, with nitrogen as carrier gas at a flow rate of 35 ml/min.

β-OH myristic acid was identified by comparison with that found in the LPS of Escherichia coli wr96. A plot of logarithm of retention time versus number of carbon atoms was used to identify β-OH-10:0 and β-OH-12:0 fatty acids.

Limulus lysate assay for endotoxin. Lipopolysaccharides were tested for gelling activity by the Limulus E-Toxate kit (Sigma). All tests were incubated at 37 °C for 30 min and a positive reaction was adjudged to be a firm gelation.

Mouse assay for endotoxin. Actinomycin D (Merck, Sharp & Dohme), 12.5 μg in sodium phosphate-buffered 0.85 % NaCl, was injected intraperitoneally into 25 g TO white female mice using disposable syringes (Dowling & Feldman, 1970). After 3 h samples (0.1, 0.3 and 0.5 μg) of LPS prepared by the phenol–water method from strains G2, G4, G50, F62 and P9, and LPS from strain A24 prepared by hydrolytic enzymes, were administered in phosphate-buffered saline to groups of six mice. Deaths were recorded and the LD₅₀ values calculated after 6 days by the method of Litchfield & Wilcoxon (1949).

RESULTS

Yields of N. gonorrhoeae and extracted LPS

Yields of N. gonorrhoeae grown in stirred culture were approximately 1 to 2 g wet wt/l for freshly isolated strains, and 3 to 4 g wet wt/l for old laboratory strains. Electron micrographs of the gonococci negatively stained with 1 % uranyl acetate show long projections, apparently derived from the outer envelope, extending from the bacterium (Fig. 1). Presumably these projections, which break off into vesicles, contain LPS. Yields of LPS from all strains were 0.1 % of the wet weight.

The purity of our preparations was illustrated when all LPS gave firm gelations with limulus lysate at 37 °C for 30 min at concentrations down to 30 ng/ml. All LPS preparations were fatal to mice when administered in submicrogram amounts together with the immuno-suppressant actinomycin D; the LD₅₀ varied from 4 μg/kg in the case of P9 to 16 μg/kg for G50.

Spectrophotometric scans of LPS dissolved in 0.1 M-NaOH revealed negligible absorption at 260 and 280 nm. The Lowry et al. (1951) test indicated that the preparations contained 2.8 to 3.7 % (w/w) protein (Table 1), but acid hydrolysis revealed only traces of glutamic acid, alanine and serine. This protein could not be removed by repeated washing and may have been associated with the LPS, perhaps covalently linked to the hexosamine of lipid A (Wober & Alaupović, 1971). Our preparations were more pure than those reported by Maeland & Kristoffersen (1971), whose preparations contained 11 to 14 % (w/w) protein. No ethanolamine was detected; ethanolamine was also absent from other species of

Neisseria (Adams, 1971). Strain G4 revealed traces of 2,6-diaminopimelic acid on paper chromatography of acid hydrolysates, indicating a slight degree of contamination with peptidoglycan.

Hydrolysis of polysaccharide from lipid A

To obtain information about the distribution of components in the lipopolysaccharides, mild hydrolysis with 1 % (w/v) acetic acid at 100 °C was performed. This treatment was expected to separate lipid A and polysaccharide moieties. During hydrolysis a white precipitate (lipid A) developed and hydrolysis was stopped after 1.5 h (Wilkinson et al. 1973). Only 8.1 to 12.6 % (w/w) of the LPS was released as lipid A (designated lipid A₁) (Table 1). The time taken fully to cleave lipid A from the polysaccharide has been shown to vary considerably in Pseudomonas aeruginosa (Chester, Meadow & Pitt, 1973). Stronger hydrolysis 2 M-HCl at 100 °C for 3 h, liberated a further 26.2 to 33.4 % (w/w) of the LPS as lipid A (designated lipid A₂) (Table 1).

Chemical analysis of lipid A

Lipid A contained all the fatty acid present in the LPS. Lipid A₁ contained 51.2 to 77.5 % (w/w) fatty acid, 0.2 to 0.9 % phosphorus and 0.4 to 3.2 % glucosamine. In contrast, lipid A₂ consisted of 38.5 to 72.1 % (w/w) fatty acid, 1.2 to 1.9 % phosphorus and 18.8 to 20.9 % glucosamine (Table 2). Thus mild hydrolysis partially cleaved LPS polysaccharide and lipid A moieties and liberated labile fatty acids, but failed to cleave the linkage of hydroxy fatty acids, which are therefore thought to be in the stable amide linkage. Combined results

Tr, trace (< 1 %).

showed total lipid A accounted for 37.5 to 43.7 % (w/w) of LPS (Table 1) and contained 43.9 to 73.0 % (w/w) fatty acid, 1.0 to 1.3 % phosphorus and 14.2 to 15.5 % glucosamine. Loosely bound lipids had been removed from LPS by prior washing with chloroform-methanol and it is therefore believed that all these fatty acids were constituents of the lipid A.

Fatty acids liberated from lipid A by acid hydrolysis were analysed as methyl esters. Lipid A₁ predominantly contained 12:0, 14:0, an unidentified acid, 16:0, 18:0 and 18:1, with hydroxy acids accounting for only 5.5 to 10.8 % (w/w) (Table 3). In contrast, fatty acids present in lipid A₂ were mainly hydroxy acids, comprising 40.2 to 48.7 % (w/w) of the total fatty acid (Table 3), together with lesser amounts of 12:0, 14:0 and 18:0, as has been found in other species of Neisseria (Adams et al. 1968; Adams, 1971). Associated lipids, removed from the LPS by prior washing with chloroform-methanol, represented 2 to 4 % of the dry weight of LPS. The fatty acid composition of the loosely bound lipids from strains G2, G4, G50 and F62 consisted predominantly of 16:0, 18:0, 18:1 and 20:1 (Table 4) which have been found in other strains of N. gonorrhoeae (Yamakawa & Ueta, 1964). In contrast, P9 consisted mainly of a fatty acid which has not been characterized completely but was almost certainly 13:0 cyclopropane, with lesser amounts of 16:0, 18:0, 18:1 and 20:1 (Table 4).
Chemical analysis of polysaccharide moiety

Paper chromatography revealed glucose, galactose, glucosamine, heptose and KDO, confirming earlier results with other strains of *N. gonorrhoeae* (Yamakawa & Ueta, 1964; Maeland & Kristoffersen, 1971). The heptose co-chromatographed with L-glycero-D-mannoheptose found in the LPS of *E. coli* Wf96. Comparison of components present in the LPS preparations is shown in Table 1. Identification of galactose and glucose was performed by g.l.c. of their alditol acetates which gave a molar ratio of galactose to glucose of 2:1 in all strains. LPS from a duplicate culture of strain P9 analysed by Galactostat and Glucostat reagents contained 3.5% (w/w) galactose to 1.8% glucose, indicating consistent growth conditions. Measurement of the molar ratios of sugars in the LPS of P9 indicated glucose 1, galactose 2, glucosamine 4, heptose 2, KDO 3.

No evidence was obtained for the presence of any O-antigen chains. In *Citrobacter freundii*, LPS containing rhamnose and dideoxyglucose entered the phenol phase or was obtained from the interphase of phenol-water extraction (Raff & Wheat, 1968). By preparing enzyme-extracted LPS (Lehrer & Nowotny, 1972) from penicillin-sensitive and penicillin-resistant gonococci we have excluded the possibility of LPS being lost in this way. Protein and KDO determinations on the enzyme-isolated LPS from strains P9 and A24 revealed 3.6 and 4.4% (w/w) KDO and 36 and 49.5% (w/w) protein, respectively. Acid hydrolysis and paper chromatography revealed glucose, galactose, heptose, KDO and glucosamine, identical to those components present in phenol-water-extracted LPS. No deoxy-, dideoxy- or N-acetylated sugars, typical of O-antigen chains, could be detected.

**DISCUSSION**

Of the strains of *N. gonorrhoeae* used in this study, strain P62 colony type 1 has been used to infect human volunteers (Kellogg et al. 1963) while strain P9 has caused an accidental eye infection in our laboratory. Under the conditions of growth described we were unable to detect significant differences in LPS composition between these strains and avirulent colony type 4 strains G2, G4 and G50. The LPS of strain P9 consisted of lipid A covalently linked to 3 molecules of KDO, 2 of heptose, 1 of glucose, 2 of galactose and 4 of glucosamine. These ratios are compatible with a structure analogous to the basal region of the LPS of the Enterobacteriaceae (Osborn et al. 1964). Our analysis of LPS prepared by enzyme hydrolysis excluded the possibility that the failure to find evidence for an O-antigen side chain was due to loss during phenol-water extraction. Strain P9, like gonococci in the natural infection (Ward, Watt & Glynn, 1970) is relatively resistant to killing by antibody and complement. Gonococci therefore differ from *Salmonella*, where the O-antigen side chain of LPS is important both in virulence and resistance to killing by antibody and complement (Nelson & Roantree, 1967). Our analysis of LPS from strains G2, G4 and G50 showed no marked difference between the strains, yet antisera raised against G50 and G4 were type-specific in the bactericidal reaction whereas strain G2 was unusually sensitive to the natural antibodies of normal human serum (Glynn & Ward, 1970). Glynn & Ward (1970) suggested that the antigens involved were LPS. Structural differences in the simple LPS of gonococci could produce antigenic variations accounting for the four serological groups which they proposed. However, the absence of an O-antigen side chain would seem to preclude the possibility of devising a complex typing system comparable to the Kaufmann-White scheme (Kaufmann, 1966) successfully used in epidemiological studies of Salmonella infections.

Some 50% of patients with gonorrhoea showed an increased titre of antibodies reactive...
with gonococcal LPS. However, 15% of normal individuals had cross-reacting antibodies (Watt et al. 1971). The fact that the LPS of other Neisseria such as N. perflava (Adams et al. 1968) have essentially similar constituents to the LPS of N. gonorrhoeae suggests that production of the cross-reacting antibodies might have been stimulated by commensal Neisseria growing on mucosal surfaces. If further work confirms this, there can be little hope of developing a useful serological test for gonorrhoea based on LPS antigens.

The lipid A moieties in all five strains contained glucosamine to which was joined phosphate groups and fatty acids, principally hydroxy-acids which, in view of their resistance to acid hydrolysis, were presumed to be amide linked. The composition is comparable to that found in the commensal Neisseria (Adams et al. 1968; Adams, 1971) and is essentially similar to the lipid A of salmonellae (Rietschel et al. 1972). In Salmonella the determinant of endotoxicity of the LPS is lipid A, linked ketosidically to KDO, the remaining carbohydrate of the LPS being unimportant in toxicity (Rietschel et al. 1971). We have shown that the simple lipopolysaccharides of all the gonococcal strains tested were potent endotoxins. We do not know if this LPS plays a role in gonococcal virulence. However, growing gonococci bud off
large amounts of outer envelope which must contain the endotoxin (Fig. 1). This material could be involved in the interaction between host and pathogen.

Maness & Sparling (1973) have suggested that a single gene may control the response of *N. gonorrhoeae* to antibiotics, perhaps by altering the permeability of the cell envelope. In *P. aeruginosa*, resistance to penicillin has been correlated with the presence of a side chain containing rhamnose, glucosamine and mannose in the LPS (Meadow, 1972). This does not seem to be the case in *N. gonorrhoeae* 224, which had the same LPS carbohydrate content as the penicillin-sensitive strains.

We are grateful to the Medical Research Council for a project grant, and to the Royal Society for a gas chromatograph. We thank Dr B. M. Wilson for his gift of KDO.
