The Role of Glucose Limitation
in the Regulation of the Transport of Glucose, Gluconate and
2-Oxogluconate, and of Glucose Metabolism in
Pseudomonas aeruginosa

SUMMARY

The pathway of glucose metabolism in Pseudomonas aeruginosa was regulated by the availability of glucose and related compounds. On changing from an ammonium limitation to a glucose limitation, the organism responded by adjusting its metabolism substantially from the extracellular direct oxidative pathway to the intracellular phosphorylative route. This change was achieved by repression of the transport systems for gluconate and 2-oxogluconate and of the associated enzymes for 2-oxogluconate metabolism and gluconate kinase, while increasing the levels of glucose transport, hexokinase and glucose 6-phosphate dehydrogenase. The role of gluconate, produced by the action of glucose dehydrogenase, as a major inhibitory factor for glucose transport, and the possible significance of these regulatory mechanisms to the organism in its natural environment, are discussed.

INTRODUCTION

Glucose metabolism in Pseudomonas aeruginosa is complex (Fig. 1), involving both direct oxidative and phosphorylative routes of metabolism (Stokes & Campbell, 1951; Claridge & Werkman, 1953, 1954; Wang, Stern & Gilmour, 1959; Roberts, Midgley & Dawes, 1973). This apparent complexity of metabolism has been clarified by the discovery that these two routes occur in different compartments of the cell. Thus, the enzymes of the direct oxidative pathway, glucose dehydrogenase and gluconate dehydrogenase, are oriented in the cytoplasmic membrane in such a manner that they oxidize their substrates extracellularly, i.e. in the periplasmic space (Midgley & Dawes, 1973; Roberts et al., 1973). The products of their activity, gluconate and 2-oxoglucunate respectively, are taken up by specific transport systems before their intracellular phosphorylation (Fig. 2). 2-Oxoglucunate 6-phosphate is then reduced to gluconate 6-phosphate (Roberts et al., 1973). Glucose, which is taken up by a separate transport system of rather broad specificity (Midgley & Dawes, 1973), is phosphorylated and oxidized to gluconate 6-phosphate, so that the metabolism of glucose, gluconate and 2-oxoglucunate converges on gluconate 6-phosphate, which is further metabolized principally via the Entner–Doudoroff route but also by the pentose phosphate pathway (Wang et al., 1959).

Previously we have studied the regulation of the enzymes of glucose catabolism by citrate under conditions of nitrogen-limitation in a chemostat (Hamlin, Ng & Dawes, 1967; Ng & Dawes, 1973) and more recently this work has been extended to include also the regulation of the transport systems for glucose, gluconate and 2-oxoglucunate (Whiting, Midgley &

* Present address: Department of Biochemistry, University of Nottingham.
Control of glucose metabolism in *P. aeruginosa* Dawes, 1976). Conditions of nitrogen limitation were chosen, to enhance catabolite repression by carbon compounds.

In its natural environment, however, *P. aeruginosa* will also encounter conditions of carbon limitation and we have therefore compared the effects of glucose limitation with nitrogen limitation on the transport systems for glucose, gluconate and 2-oxoglucionate, and on enzymes characteristic of the extracellular and intracellular pathways of glucose metabolism. Evidence is presented which reveals that *P. aeruginosa* responds to a glucose limitation by switching its metabolism of glucose substantially from the extracellular direct oxidative pathway to the intracellular phosphorylative route. A preliminary account of these findings has been presented by Dawes, Midgley & Whiting (1976).

METHODS

Organism. The organism used was *Pseudomonas aeruginosa* PAO1, kindly provided by Professor B. W. Holloway.

Growth and maintenance of cultures. Routine maintenance, batch growth of the organism, harvesting procedures and the preparation of bacterial extracts were as previously described (Ng & Dawes, 1973; Midgley & Dawes, 1973). For chemostat inocula the organism was subcultured at least ten times in the appropriate medium.

The chemostat was identical to that used by Ng & Dawes (1973), the dilution rate being 0.41 h⁻¹ throughout. Medium for continuous cultivation was prepared in 20 l batches which were sterilized by filtration through a Sartorius filter (142 mm diam, pore size 0.22 μm) at 137.5 kN/m² (20 lb/in²). The medium contained (g/20 l): KH₂PO₄, 108; (NH₄)₂SO₄, 31.7 (for nitrogen-limited growth) or 63.4 (for glucose-limited growth); nitrilotriacetic acid, 5.73; trace metals solutions 1 (100 ml), 2 (105 ml) and 3 (2 ml) (Ng & Dawes, 1973); glucose, 162.2 (for nitrogen-limited growth) or 108 (for glucose-limited growth).

Transport studies. These were performed as described by Midgley & Dawes (1973). Organisms were separated from the suspending medium by rapid filtration and subsequently washed at 18 °C with a solution of the following composition: 4 mM-MgSO₄, 0.342 M-NaCl in 0.067 M-potassium phosphate buffer adjusted to pH 7.1 with 10 M-NaOH. The specific activities and final concentrations of the substrates used were: glucose, 100 μCi/pmol, 5 μM; sodium gluconate, 3.4 μCi/pmol, 50 μM; sodium 2-oxoglucconate, 0.1 μCi/pmol, 3 μM. The bacterial density was adjusted so that linear initial rates were measured in all assays. The radioactivity accumulated by the organism was determined as described by Midgley & Dawes (1973).

Enzyme assays. The enzymes of glucose and 2-oxoglucconate catabolism were assayed under the conditions described by Ng & Dawes (1973) except that glucose dehydrogenase was assayed in the presence of phenazine methosulphate (2 mM). The combined activity of α-oxoglucconate kinase and α-oxoglucconate 6-phosphate reductase was assayed in the system: tris-HCl buffer (0.12 M, pH 7.5), 1.0 ml; MgCl₂ (0.6 M), 0.1 ml; NADPH (2 mM), 0.1 ml; ATP (36 mM, pH 7.5), 0.3 ml; sodium 2-oxoglucconate (50 mM), 0.1 ml; and distilled water to 2.8 ml. The reaction was monitored by following the ATP- and 2-oxoglucconate-dependent oxidation of NADPH at 340 nm after addition of 0.1 ml bacterial extract.

Preparation of 2-oxo[U-¹⁴C]glucconate. This method was based on the observations of Stokes & Campbell (1951) who showed that dried cells of *P. aeruginosa* converted glucose quantitatively to 2-oxoglucconate. A suspension of dried *P. aeruginosa* PAO1 was prepared from an overnight culture grown in nutrient broth plus 1% (w/v) glucose. Bacteria were harvested, washed and finally resuspended in distilled water. The suspension was dried by rotary evaporation at 40 °C under reduced pressure. The dried organism was powdered and stored at 4 °C. The conversion of [U-¹⁴C]glucose to 2-oxoglucconate was performed in a Warburg manometer to monitor the extent of the reaction. Manometer flasks contained, in the main compartment, 0.5 ml bacterial suspension (at 40 mg dried organism/ml distilled water), and 1.5 ml potassium phosphate buffer (0.067 M, pH adjusted to 7.1 with 10 M-NaOH). The side arm contained either glucose (5 μmol, 200 μCi) or, for endogenous controls, water (0.5 ml). The centre well contained a roll of Whatman No. 541 filter paper and 0.2 ml of 20% KOH. After equilibration and mixing of the flask contents, oxygen uptake was followed for 2 h, after which the endogenous and reaction rates coincided. The flask contents were then centrifuged (5000 g, 10 min), and the supernatant was retained and the pellet washed with distilled water. The wash fluid and the original supernatant were

Combined and treated at 60 °C with ethanol (final concentration 70%, v/v). The protein precipitate was removed by filtration, and the filtrate rotary-evaporated to dryness at 40 °C under reduced pressure. The residue was redissolved in water (0.5 ml) and subjected to electrophoresis, using Whatman No. 541 paper on a Shandon high-voltage electrophoresis apparatus operated at 3 kV for 2 h. The solvent system used was formic acid-acetic acid-water (50:156:1794 by vol., pH 2.0). The paper was dried and the area corresponding to 2-oxoglucconate was eluted with distilled water. The resulting solution was taken to dryness by rotary evaporation and the electrophoretic separation repeated. The purity of the final product was greater than 99%, as assessed by treating the radiochemical with various enzymes (gluconate kinase alone, or plus gluconate 6-phosphate dehydrogenase) and examining the incubation mixture for expected products (gluconate 6-phosphate and ribulose 5-phosphate, respectively) in the electrophoresis system described.

Analyses. Protein was estimated by the method of Gornall, Bardawill & David (1949), with correction for the biuret-positive material in the glycyglycine buffer used to prepare bacterial extracts. Glucose was determined with a glucose oxidase kit (Boehringer Corp., London). 2-Oxoglucconate was determined by the method of Lanning & Cohen (1951). Glucose also reacts in this assay, though the sensitivity is 40-fold lower; its contribution was assessed from its known concentration in the sample, using a suitable calibration curve, and appropriate adjustment made in determining 2-oxoglucconate. Gluconate was determined by coupling gluconate kinase with gluconate 6-phosphate dehydrogenase according to the Boehringer handbook. Other analyses were as performed by Ng & Dawes (1973).

Chemicals. [U-14C]glucose and [U-14C]gluconate were obtained from the Radiochemical Centre, Amersham, Buckinghamshire. Calcium 2-oxoglucconate was obtained from Sigma and converted to its sodium salt by treatment with Dowex 50 (H+ form) followed by neutralization with 10 M-NaOH.

RESULTS AND DISCUSSION

A change of the limiting nutrient from ammonium to glucose had a profound effect on the transport systems (Table 1). Thus the level of the glucose transport system increased some fivefold, whereas the levels of the transport of gluconate and 2-oxoglucconate decreased respectively about seven- and fivefold. The induction of the glucose transport system that occurred on shifting from a nitrogen limitation to a glucose limitation probably reflected the decreased concentration of gluconate in the medium (Table 2), since we have shown, under conditions of nitrogen limitation, that gluconate produced by the extracellular activity of glucose dehydrogenase is a major factor in repressing glucose transport activity (Whiting...

* The two values quoted are the means of duplicate determinations performed on two separate culture samples from each steady state.

The fall in the levels of the gluconate and 2-oxogluconate transport systems can be attributed to the reduction in concentration of gluconate and 2-oxogluconate respectively, since we have also demonstrated (Whiting *et al.*, 1976) that glucose must be converted to these substrates for the induction of their transport systems. The relatively high $K_m$ values (both about 1 mM) of the enzymes of the extracellular pathway (Midgley & Dawes, 1973; Roberts *et al.*, 1973) compared with the $K_m$ for glucose transport (8 μM), plus the observed induction of the glucose transport system, presumably results in a much diminished flux of carbon through the extracellular pathway under conditions of glucose limitation when the residual glucose concentration is approximately 0.1 mM.

The capacity of the organism to transport 2-oxogluconate was large compared with the other two transport systems when grown under nitrogen limitation, conditions which produced approximately 5 mM-2-oxogluconate in the medium. Even higher activities of this transport system have been detected in the organism grown in batch culture on gluconate when, by a conventional Lineweaver-Burk plot, the $K_m$ and $V_{max}$ for 2-oxogluconate uptake were determined as 0.9 mM and 118 μmol/min/g dry wt respectively. The relatively high activity of this transport system, under conditions of nitrogen limitation, may reflect the excess activity of the extracellular pathway enzymes [approximately 10- to 20-fold (Midgley & Dawes, 1973; Roberts *et al.*, 1973)], compared with the activities of the glucose and gluconate transport systems.

The switch from the extracellular pathway to the intracellular pathway when the organism is subjected to a change from a nitrogen to a glucose limitation is also reflected by the levels of the enzymes of glucose catabolism. Glucose limitation resulted in a marked decrease in the levels of gluconate dehydrogenase, glucose dehydrogenase, gluconate kinase, and the enzymes of 2-oxoglucanate catabolism assayed as a combined activity (Table 3). In contrast, the enzymes which initiate the intracellular phosphorylative metabolism, namely hexokinase and glucose 6-phosphate dehydrogenase, were substantially increased.

As previously noted, the extracellular and intracellular routes converge on gluconate 6-phosphate for entry to the Entner-Doudoroff pathway and the enzymes of this latter sequence are not significantly affected by the switch from nitrogen to glucose limitation. However, the activity of one of the enzymes of the tricarboxylic acid cycle, isocitrate dehydrogenase, falls by two-thirds.

It is clear, therefore, that *P. aeruginosa* responds to a limited supply of carbon by diverting its metabolism of glucose substantially from the extracellular direct oxidative pathway to the intracellular phosphorylative route. Despite the high steady state concentration of 2-oxoglucanate produced under conditions of nitrogen limitation in the chemostat, and there-

* Nitrogen-limited medium contained 12 mm ammonium sulphate and 45 mm glucose. Glucose-limited medium contained 24 mm ammonium sulphate and 30 mm glucose. The bacterial cell density was approximately 2 mg dry wt/ml for both media.

† The two values quoted are the mean of duplicate determinations performed on two separate culture samples from each steady state.
fore lost in the outflow, there does not appear to be a large wastage of glucose carbon since the steady state rate of glucose utilization under conditions of nitrogen-limitation is only slightly greater (6.8 against 6.2 mmol/h/g dry wt) than the rate under conditions of carbon limitation.

Our findings thus offer some support for the suggestion that the persistence, during the course of evolution, of the extracellular pathway of glucose metabolism in *P. aeruginosa*, and in *Pseudomonas fluorescens* (Eisenberg et al., 1974), has permitted these organisms, in their natural habitat, to sequester glucose as gluconate and 2-oxoglucuronate, compounds which are not so readily utilized by various other micro-organisms that may effectively compete for the available glucose. Thus, when the glucose supply is restricted, *P. aeruginosa* responds by adjusting its metabolism so that the available carbon source is taken up as rapidly as possible. *Pseudomonas aeruginosa* therefore affords an excellent example of microbial response to a low-nutrient environment, as discussed by Tempest (1976) for *Klebsiella aerogenes* in respect of both ammonium and glycerol uptake.

We thank the Science Research Council for the award of a Research Studentship to P.H.W.
