Peptococcaceae, a New Family To Include the Gram-Positive, Anaerobic Cocci of the Genera *Peptococcus*, *Peptostreptococcus*, and *Ruminococcus*

MORRISON ROGOSA

Microbial-Physiology Section, Laboratory of Microbiology and Immunology, National Institute of Dental Research, Bethesda, Maryland 20014

*Peptococcaceae* is proposed as a new family in the order *Eubacteriales* to include three genera of presently known gram-positive, anaerobic, coccal organisms: *Peptococcus* Kluyver and van Niel, *Peptostreptococcus* Kluyver and van Niel, and *Ruminococcus* Sijpestein. The type genus of this family is *Peptococcus*. Descriptions of these taxa are given, and where necessary the original descriptions have been expanded and brought up to date.

The genera *Peptococcus* and *Peptostreptococcus* were named by Kluyver and van Niel (1), who assigned them to the tribes *Micrococcaceae* and *Streptococcaceae*, respectively, within the family *Micrococcaceae*. *Peptococcus* was the tenth listed genus in *Micrococcaceae* and was described as follows.

"10. *Peptococcus* nov. gen. 2) Spherical cells, either immotile or motile. No endospores formed. Chemoheterotrophic, anaerobic, capable of fermenting protein decomposition products. Gram positive. The type species is *Peptococcus* niger (Hall)."

The type species is *Peptococcus* niger (Hall).

"2) The various anaerobic, Gram positive cocci placed by Prévot (l.c.) in the genera *Diplococcus*, *Gaffkya*, *Staphylococcus* and *Micrococcus* might well be united in this genus, as long as further particulars regarding their katabolism are lacking."

*Peptostreptococcus* was the first listed genus in *Streptococcaceae* and was defined as follows (1).

"1. *Peptostreptococcus* gen. nov. Spherical cells, generally occurring in chains. Immotile. No endospores formed. Chemoheterotrophic, anaerobic, capable of fermenting protein decomposition products with the formation of carbon dioxide, hydrogen, and other unknown products. Gram positive. The type species is *Peptostreptococcus* anaerobius (König et Menge)."

From the foregoing, it is clear that *Peptostreptococcus* was differentiated from *Peptococcus* mainly by the ability of *Peptostreptococcus* to form chains; both genera were "capable of fermenting protein decomposition products." In the case of *Peptostreptococcus*, "carbon dioxide, hydrogen, and other unknown products" accumulated in cultures. Adequate analytical methods for the determination of lactic acid were then available, and it is significant that there was no mention of lactic acid as a product with either genus (1). Clearly, lactic acid could have been nothing more than a very minor catabolic product, at best.

*Streptococcus* was the second genus listed in the tribe *Streptococcaceae* (1); however, in emphatic contrast to *Peptostreptococcus*, the genus *Streptococcus* fermented carbohydrates "with the practically exclusive formation of lactic acid." As is pointed out later in this paper, *Peptostreptococcus* and *Streptococcus* have often been confused, simply because both genera consist of chain-forming spherical organisms. There is little or no doubt that investigators generally ignored the great catabolic differences between these genera (2; Bergey's Manual of Determinative Bacteriology, 7th ed.).

In addition to *Peptococcus* and *Peptostreptococcus*, the genus *Ruminococcus* Sijpestein has never been unequivocally allocated to any suprageneric taxon. Sijpestein (Ph.D. Thesis, University of Leiden, the Netherlands, 1948) diffidently suggested that *Ruminococcus* be included with *Streptococcus* in *Streptococcaceae*; however, she and subsequent investigators clearly recognized that the organisms comprising *Ruminococcus* are not lactic acid bacteria because lactate is not a major product, but, if present, is rather generally a very minor or trace
constituent of the fermentation products. This, plus the fact that strains of *Ruminococcus*, have been variously described as gram-positive, gram-variable, or gram-negative, tended to obfuscate the relationship of these cellulolytic cocci to organisms in other genera and suprageneric taxa. Recently, however, electron microscopic examination of thin sections of cells from authentic cultures of *Ruminococcus flavefaciens*, the type species, and from *R. albus*, the other known species, revealed that cell walls of all examined cultures have the generally characteristic dense, not triple-tracked anatomy associated with gram-positive cells (Roger M. Cole, *personal communication*; details to be published subsequently). Therefore, whatever the reasons for variations in Gram stain results in the hands of different investigators, *Ruminococcus* is here considered to be gram-positive.

The author recently proposed (3) the family name *Veillonellaceae* to accommodate the known gram-negative, anaerobic cocci comprising the genera *Veillonella* Prévot, *Acidaminococcus* Rogosa, and *Megasphaera* Rogosa.

Similarly, the family name *Peptococcaceae* is here proposed for the gram-positive, anaerobic cocci of the genera *Peptococcus* Kluyver and van Niel, *Peptostreptococcus* Kluyver and van Niel, and *Ruminococcus* Sijpestein. The type genus of this family is *Peptococcus*. Updated descriptions of these taxa follow.

**Peptococcaceae fam. nov.**

Pepto-occ.ca.ceae. M. L. mas. n. *Peptococcus* type genus of the family; -aceae ending to denote a family; M. L. fem. pl. n. *Peptococcaceae* the *Peptococcus* family.

Cocci varying in diameter (0.5 to 2.5 μm). Occur singly, in pairs, tetrads, and irregular masses, occasionally in three-dimensional cubic packets. Some organisms may form short or long chains with some elongation of individual elements. Flagella, motility, and endospores are absent. Gram-positive but may stain equivocally. Anaerobic. Chemoorganotrophic with complex nutritional requirements. Gas, consisting of CO₂ and usually H₂, is produced in cultures from amino acids, or carbohydrates, or both; H₂S may also be detectable. Carbohydrates may or may not be fermented. In complex media the major nongaseous products are lower fatty acids; in some cases, succinate or ethanol may also be major products. Lactate, if produced, is generally not a major product.

The genera of *Peptococcaceae* are (i) *Peptococcus* Kluyver and van Niel, 1936; type species: *P. niger* (Hall) Kluyver and van Niel; (ii) *Peptostreptococcus* Kluyver and van Niel, 1936; type species: *P. anaerobius* (Krönig) Kluyver and van Niel; (iii) *Ruminococcus* Sijpestein, 1948; type species: *R. flavefaciens* Sijpestein.

According to the classification of the bacteria in *Berger's Manual*, 7th ed., the family *Peptococcaceae* is placed in the order *Eubacteriales*.

The descriptions of *Peptococcus*, *Peptostreptococcus*, and *Ruminococcus* are updated as follows (for each taxon, the characters in italics are the major defining ones and are possessed by all members of the taxon).

**Peptococcus** Kluyver and van Niel, 1936.

Spheres, usually 0.5 to 1.0 μm, exceptionally up to 1.6 μm, in diameter. Occur singly, in pairs, tetrads, or irregular masses but not in three-dimensional cubic packets. Long chains are not formed, and short chains are infrequent. Flagella, motility, and spores are absent. Gram-positive. Anaerobic. Weak catalase activity may be present. Chemoorganotrophic with complex nutritional requirements. Peptones, amino acids, and purines or pyrimidines can be used as major energy sources. In complex media, various combinations of the C₁ to C₄ lower volatile fatty acids, CO₂, H₂, and ammonia tend to be major products from amino acids; some lactate is also produced from histidine, but lactate is not a major product in glucose complex media. Lactate and malate are not fermented. A number of organisms produce gas from pyruvate but generally not from citrate or tartrate. Saccharolytic activity is often limited or absent, and added carbohydrates do not appear to be essential for growth (although growth may occasionally be enhanced) in complex media. With some organisms, the addition of fatty acid compounds (such as olate or Tween 80) to complex media may stimulate growth or carbohydrate fermentation.

Isolated from the human female urogenital tract, the human intestinal and respiratory tracts, inflamed appendices, a case of cystitis, pleurisy, the gums, postpartum septicaemia, tonsils, plasma, skin, tidal bay mud, and caseous lymphadenitis in sheep. Sensitive to penicillin G (1 to 10 units/ml, and often less than 1 unit/ml). Pathogenicity is probable but at present not clear because isolations are very frequently from sites where other potential pathogens are present.

Type species: *P. niger* (Hall) Kluyver and van Niel.

**Peptostreptococcus** Kluyver and van Niel, 1936.

Spherical to ovoid cells sometimes lengthened to appear pointed; diameter, 0.7 to 1.0 μm, occasionally somewhat less. Occur in pairs.
and in short or long chains. No flagella. No motility. No spores. Gram-positive. Anaerobic. Complex media for growth. Where tested, strains have been sensitive to penicillin G (10 units/ml, and often less than 1 unit/ml). Catalase negative. Nitrates not reduced. Indole generally not produced. Gelatin generally not liquefied, and coagulated proteins not attacked. Very rarely hemolytic. In complex media, a fetid odor and gas (mainly CO₂, with some H₂ and H₂S) and large quantities of C₁ to C₆ volatile acids are produced; lactate is either not produced or is present in at best trace amounts. Ammonia is produced, but alkaline reaction may be prevented by acid produced in carbohydrate media; acetylmethylcarbinol, amines, and alcohols may also be produced. Acid and gas are produced from pyruvate and glucose, but with pyruvate as the substrate, the pH of the medium is not necessarily lowered because of the occasional production of acids weaker than pyruvate.

Isolated from the normal and pathological female genital tract and blood in puerperal fever, from respiratory and intestinal tracts in normal humans and animals, from the oral cavity, from pyogenic infections, putrefactive war wounds, and appendicitis. May be pathogenic.

Type species: *P. anaerobius* (Krönig) Kluyver and van Niel.

Further comment. In the author's opinion, this expanded, up-dated description is consistent with the limited original description of *Peptostreptococcus* (1) but is more accurate and covers a more homogeneous taxon than any previous description of which he is aware. The above description covers the type species, *P. anaerobius*, as well as the generally similar organisms *P. foetidus* (Veillon) Smith, *P. putridus* (Schottmüller) Smith, and *P. lanceolatus* (Prévot) Smith (4). It is reemphasized that these are not lactic acid bacteria. A second group previously included in *Peptostreptococcus* (Bergey's Manual, 7th ed.) are here excluded according to the present genus description; these organisms are *P. micros* (Prévot) Smith, *P. parvulus* (Weinberg et al.) Smith, *P. intermedius* (Prévot) Smith, and *P. evolutus* (Prévot) Smith. These organisms do not produce fetid odors, do not produce gas in culture of from pyruvate, do not produce C₄ to C₆ volatile acids, but rather produce lactic acid as a major product. These lactic acid bacteria also have the other general characteristics of *Streptococcus* and are simply more anaerobic or less aerotolerant than most members of the genus *Streptococcus*. Indeed, many strains of the presently discussed taxon,
particularly those often designated as *P. intermedius* and *P. evolutus*, grow well in air after one or more passages.

A third heterogeneous group, previously described (4), also included in *Peptostreptococcus* is not herein included because the members of this group are not covered by the presently given generic description; these are *P. magnus* (Prévo) Smith, *P. plagarumbelli* (Prévo) Smith, *P. paleopneumoniae* (Prévo) Smith, and *P. morbillorum* (Prévo) Smith. The first two appear to have morphological characteristics consistent with those of *Peptococcus*, and the latter two organisms are lactic acid bacteria having characteristics consistent with those of organisms in the genus *Streptococcus*.

*Spherical to somewhat elongated cocoid cells* with a diameter from 0.7 to 1.2 µm. When elongated, the cells tend to have rounded or flattened ends rather than pointed. When in the diplococcal arrangement, the sides of the cells may be flattened, thus resembling neisseriae and pediococci. Occur as single cells, diplococci, or short chains (usually 3 to 4 cells) or as chains of 8 to 50 or more cells. *In young culture, the cells contain an iodophilic reserve polysaccharide* (glucose polymer) which may rapidly disappear in the stationary phase of growth. Endospores and motility are absent. Gram-positive but may stain ambiguously. Anaerobic. Chemoorganotrophic. Complex nutritional requirements for growth are satisfied by rumen fluid or fecal extracts in usual media. The majority of strains grow in a defined medium containing B vitamins, cellobiose, minerals, ammonia, sulfide, CO₂, acetate, and one or more of the branch-chained acids: isovalerate, isobutyrate, and 2-methyl-butirate. Ammonia is essential as the main nitrogen source. Amino acids are generally poorly utilized for growth, although methionine and vitamin B₁₂ are sometimes required. Catalase, indole, and H₂S are not produced. Starch is not degraded, nitrate is not reduced, ammonia is not produced from amino acids or peptides, the Voges-Proskauer reaction is variable, and a small minority of strains liquefy gelatin. *Cellobiose is digested* (a very few noncellulolytic strains have been isolated). *Cellobiose is fermented*, and about 85% of the strains ferment xylan. A given strain may attack no other sugars or may attack one or more of the following: glucose, D-xylene, esculin, fructose, lactose, and L-arabinose. No acid is produced from a wide variety of other carbohydrates and polyols. In media containing bicarbonate and gassed with CO₂, major products from cellobiose are acetic and formic acids; ethanol and/or succinic acid may also be major products; however, when ethanol is a major product, there is generally more hydrogen and little or no succinic acid, and when succinate is a major product there is little hydrogen and little or no ethanol. Lactic acid, if produced, is generally a minor product; methane and fatty acids containing three or more carbon atoms are not formed. Isolated from bovine and ovine rumens and from ceca of rabbits and guinea pigs. Probably widely distributed in the rumens of *Ruminantia* and in the cecum and colon of herbivores, and thought to play an important role in the fermentation of cellulose in these organs. The guanine plus cytosine of the deoxyribonucleic acid ranges from 39.8 to 45.4 moles per cent (Tm).

Type species: *R. flavefaciens* Sijpestein.
