Separation of *Alcaligenes denitrificans* sp. nov., nom. rev. from *Alcaligenes faecalis* on the Basis of DNA Base Composition, DNA Homology, and Nitrate Reduction

H.-J. Rüger* and T. L. Tan

Institut für Meeresforschung, Am Handelshafen 12, D-2850 Bremerhaven, Federal Republic of Germany

“*Alcaligenes denitrificans*” Leifson and Hugh 1954 was not included in the Approved Lists of Bacterial Names and hence has no standing in bacteriological nomenclature. However, *Alcaligenes faecalis* DSM 30026 ("A. denitrificans" Leifson and Hugh 1954, type strain) has a DNA base composition of 69.1 ± 0.3 mol% G+C, whereas *A. faecalis* DSM 30030 (type strain) and *A. faecalis* DSM 30033 ("A. odorans," type strain) have 57.6 ± 0.5 and 55.3 ± 0.8 mol% G+C, respectively. DNA hybridization revealed homologies of 27% between *A. faecalis* DSM 30026$^\text{T}$ and strain DSM 30030$^\text{T}$, 26% between *A. faecalis* DSM 30026$^\text{T}$ and strain DSM 30033$^\text{T}$, but 71% between strains DSM 30030$^\text{T}$ and DSM 30033$^\text{T}$. A yellow fluorescent pigment in King medium B was produced by *A. faecalis* strains DSM 30030$^\text{T}$ and DSM 30033$^\text{T}$ but not by strain DSM 30026$^\text{T}$. Only *A. faecalis* DSM 30026$^\text{T}$ was able to grow with nitrate or nitrite as sole source of nitrogen and to reduce nitrate to nitrite and gas. All three strains reduced nitrate to nitrite, but an additional nitrogen source, e.g., ammonium ion, was necessary for the growth of strains DSM 30030$^\text{T}$ and DSM 30033$^\text{T}$. In mineral media, the nitrate reduction to nitrite and gas has been shown to be reproducible. Based on the differences among *A. faecalis* DSM 30026 and both *A. faecalis* DSM 30030$^\text{T}$ and DSM 30033$^\text{T}$, the revival of the name *Alcaligenes denitrificans* is herein proposed.

Leifson and Hugh (11) described two strains which reduced nitrate to nitrite and gas as belonging to a new species, “*Alcaligenes denitrificans*.” NCTC 8582 was designated the type strain. Based on biochemical and nutritional characteristics, Hendrie et al. (9) proposed “A. denitrificans,” “A. odorans” (Málek and Kazdová-Kožíšková Málek, Radochová, and Ly森ko 1963, and “Achromobacter arsenoxy-dans-tres” Turner 1954 as subjective synonyms of *A. faecalis* Castellani and Chalmers 1919. The description of *A. faecalis* given in *Bergey’s Manual of Determinative Bacteriology*, 8th ed. (10) follows the proposal of Hendrie et al. (9). The rejection of “A. denitrificans” was reinforced by the exclusion of this name from the Approved Lists of Bacterial Names published in 1980 (20).

In addition to other characteristics, Pichinoty et al. (17) reported a DNA base ratio of 67.3 mol% G+C for “A. denitrificans” CIP 7715$^\text{T}$ (=DSM 30026$^\text{T}$) and a DNA base ratio of 56.1 mol% G+C for *A. faecalis* CIP 6080$^\text{T}$ (=DSM 30030$^\text{T}$), regarded as “A. odorans” by Pichinoty et al. (17).

Bacteria whose genomic DNAs differ by more than 4 to 5 mol% G+C (2) or by 10 mol% G+C (23) should not be considered members of the same species.

To define the relationships among *A. faecalis* ("A. denitrificans") DSM 30026$^\text{T}$, *A. faecalis* DSM 30030 (type strain), and *A. faecalis* ("A. odorans") DSM 30033$^\text{T}$, DNA base analyses, DNA hybridization experiments, nitrate reduction to nitrite and gas, and other identification procedures were performed.

**MATERIALS AND METHODS**

**Bacterial strains.** The following strains were used in this study.

*Alcaligenes faecalis* DSM 30030 (=ATCC 8750, =CIP 6080, =NCIB 8156). Strain ATCC 8750, originally the reference strain of *A. faecalis* (9, 10), has been established as the type strain (20).

*Alcaligenes faecalis* DSM 30033 (=CCEB 554, =ATCC 15554). Strain CCEB 554 is the type strain of "A. odorans" (12), which is now regarded as a subjective synonym of *A. faecalis* (9, 10).

*Alcaligenes faecalis* DSM 30026 (=NCTC 8582, =ATCC 15173, =CIP 7715). Strain NCTC 8582 is the type strain of "A. denitrificans" (11).

Cultures of these strains were obtained from the Deutsche Sammlung von Mikroorganismen, Göttingen, Germany.

The abbreviations used in strain designations are: ATCC, American Type Culture Collection, Rockville, Md.; CCEB, Culture Collection of Entomogenous Bacteria, Prague, Czechoslovakia; CIP, Collection de l’Institut Pasteur, Paris, France; DSM, Deutsche Sammlung von Mikroorganismen, Göttingen, Federal
Biochemical and nutritional characteristics of the National Collection of Type Cultures, Central Public Health Laboratory, London, England.

Biochemical tests. The media used for determining the biochemical and nutritional characteristics of the strains have been previously described (24). The media used for detecting the amino acid decarboxylases, lipolysis, and alginate digestion were reported by Rüger and Richter (18). The growth experiments with various carbon sources were carried out in the artificial seawater medium described below (ASM + NH₄⁺, but with the respective carbon source instead of succinate). DNase activity was determined on Desoxyribonuclease Testagar (E. Merck AG, Darmstadt, Federal Republic of Germany).

DNA base composition. DNA was isolated according to the method of Marmur (14) from cells grown in ASM + NH₄⁺ as described below, but with sodium glutamate (4 g/liter) and yeast extract (50 mg/liter) instead of ammonium sulfate, sodium succinate, and vitamins. As the terminal electron acceptor instead of oxygen, 1 g of KNO₃ and 1 g of KNO₂ were added per liter for growing strains DSM 30030T and DSM 30033T and strain DSM 30026T, respectively. The medium (750 ml) was filled into 1-liter Erlenmeyer flasks and inoculated with 50 ml of a preculture grown overnight in the same medium. The cultures were incubated at 33°C for 4 days without shaking. From 4.5 liter of medium, about 2 g (wet weight) of cells were harvested by centrifugation. The use of these growth media and conditions reduced the production of an intracellular slime, which otherwise decreased the yield of DNA by about 50% (8). The slime formed a resilient substance at 60°C, the cells were lysed overnight at 33°C with sodium lauryl sulfate.

The melting temperature (Tₘ) of the DNA was determined by the method of Marmur and Doty (15) with a recording Gilford spectrophotometer (no. 250) equipped with a reference compensator, a thermocuvette, and a thermoprogrammer. The G+C content of the DNA was calculated from the Tₘ by the equation given by De Ley (5). It was necessary to use 0.1X standard saline citrate (SSC) buffer and equation 3 of Mandel and Marmur (13) for determining the high G+C content of DNA in strain DSM 30026T. DNA from Escherichia coli K-12 was used as a standard. The DNA base ratio for each strain was calculated from nine test results.

DNA hybridization. DNA hybridization was measured from renaturation rates according to the methods and conditions reported by De Ley et al. (6) and Gillis et al. (8). The isolated DNA was dialyzed against 2 liters of 2X SSC buffer for 3 days at 4°C. The buffer was replaced twice by fresh buffer solutions after 24 and 48 h. The DNA was then sheared by passing it through a French pressure cell (catalog no. 4-3399; American Instrument Co., Inc., Silver Spring, Md.) at 1.075 bar in the liquid. Normally, optimal renaturation rates are achieved in 2X SSC buffer, but the Tₘ is increased by about 4°C if the cation concentration is doubled (8). For technical reasons, Tₘ exceeding 100°C cannot be applied in the Gilford thermocuvette, and, therefore, the denaturation temperatures were lowered 16°C by the addition of 25% (vol/vol) formamide to the buffer.

The sample compartments of the thermocuvette were filled as follows: compartment 1, 2X SSC buffer as a blank; compartment 2, DNA sample A; compartment 3, a mixture (1:1) of DNA samples A and B; and compartment 4, DNA sample B. The denaturation temperature was adjusted to 96°C and maintained for 30 min after the maximal hyperchromicity had been achieved. To avoid the high absorbance of formamide at 260 nm, the optical measurements were performed at 270 nm (1). The temperature was then rapidly adjusted to 62°C, i.e., the average renaturation temperature (8) of DNA from strains DSM 30026T and DSM 30033T was lowered by 16°C. The change in absorbance, reaching linearity after a few minutes, was recorded for 40 min. Renaturation rates were determined directly from the renaturation curves in the time intervals between 6 and 36 min and 8 and 36 min after cooling the samples. The degree of DNA-DNA binding was calculated from the renaturation rates with equation 20 of De Ley et al. (6). Five renaturation experiments were performed for each combination of strains.

Nitrate reduction to nitrite and gas and nitrite reduction to gas. The medium composition used was based on an artificial seawater solution described by Burkholder (4), but with half the concentration of mineral salts. The constituents of the medium in 1,000 ml of distilled water were: NaCl, 11.738 g; KCl, 0.332 g; KBr, 0.048 g; MgCl₂·6H₂O, 5.305 g; SrCl₂·6H₂O, 0.020 g; CaCl₂·2H₂O, 0.7345 g; Na₂SO₄, 1.9585 g; NaHCO₃, 0.966 g; H₃BO₃, 0.013 g; K₂HPO₄, 0.020 g; (NH₄)₂SO₄, 1.0 g; Fe(III)-citrate, 0.0007 g; and sodium succinate (carbon source), 2.0 g. A vitamin stock solution was added (2 ml) containing per 100 ml of distilled water: biotin, 0.2 mg; nicotinic acid, 2 mg; thiamine dichloride, 1 mg; p-aminobenzoic acid, 1 mg; pantothenic acid (calcium salt), 0.5 mg; pyridoxamine, 5 mg; vitamin B₁₂, 2 mg; riboavin, 1 mg; folic acid, 0.3 mg; and myo-inositol, 0.1 mg. The pH was adjusted to 7.8. This medium, abbreviated ASM + NH₄⁺, was used for growing the precultures (2 days incubation at 24°C).

Nitrate reduction to nitrite and gas was determined in ASM + NH₄⁺ medium containing 0.5 g or 1.0 g of KNO₃ per liter (ASM + NH₄⁺ + NO₃⁻) and in the ASM + NH₄⁺ + NO₃⁻ medium without ammonium ion (ASM + NO₃⁻). A Durham tube was inserted into each test tube, which contained 10 ml of the medium. The media were inoculated with 1 drop of the precultures, and after 1, 2, and 3 days at 24°C, nitrite formation was tested with Merckoquant 1000 nitrite test sticks (16); gas formation by denitrification was detected in the Durham tubes after 7, 9, and 14 days of incubation.

Nitrite reduction to gas was observed in ASM + NH₄⁺ containing 0.5 g of KNO₃ per liter (ASM + NH₄⁺ + NO₃⁻) and in the ASM + NH₄⁺ + NO₃⁻ medium without ammonium ion (ASM + NO₃⁻). Gas formation in the Durham tubes was detected after 7, 9, and 14 days of incubation.

Nitrate and nitrite assimilation. Growth in ASM + NO₃⁻ and in ASM + NO₂⁻ media after 7 days of incubation at 24°C was used as an indication of the ability of the bacteria to assimilate nitrate or nitrite. Turbidity measurements at 578 nm were used as evidence of growth. A strain was regarded as assimili-
RESULTS

The characteristics useful in differentiating between A. faecalis DSM 30030T, A. faecalis ("A. odorans") DSM 30033T, and A. faecalis ("A. denitrificans") DSM 30026T are listed in Table 1. Other diagnostic test results obtained with A. faecalis strains DSM 30030T and DSM 30033T were identical with those reported in the description of "A. denitrificans" at the end of this paper.

The results of the DNA hybridizations showed DNA homologies of 27 ± 3.7% between strains DSM 30026T and DSM 30030T and of 26 ± 2.6% between strains DSM 30026T and DSM 30033T. However, a DNA homology of 71 ± 1.0% was found for strains DSM 30030T and DSM 30033T.

The yellow fluorescent pigments (Table 1) produced by A. faecalis DSM 30030T and DSM 30033T in King medium B were probably fluorescent. This yellow fluorescence was observed at a wavelength of 360 nm (but not at 240 nm) in a glass petri dish after removing the cover. In plastic petri dishes, pigment production was inhibited or delayed.

DISCUSSION

The differences and some similarities of the type strains of the three Alcaligenes species studied are listed in Table 1.

The DNA base compositions obtained are comparable with those reported in the literature for these strains (7, 9, 10, 17). Pichinoty et al. (17) reported 67.3 mol% G+C for "A. denitrificans" CIP 7715T (=DSM 30026T) and 56.1 mol% G+C for A. faecalis CIP 6080T (=DSM 30030T); the latter strain was assigned to "A. odorans" by Pichinoty et al. (17). According to De Ley et al. (7) and to Hendrie et al. (9), the DNAs of A. faecalis NCIB 8156T (=DSM 30030T) and A. faecalis CCEB 554T (=DSM 30033T) had 58.9 and 56.6 mol% G+C, respectively. Unfortunately, these publications (7, 9) did not contain any data about the DNA base composition of the type strain of "A. denitrificans".

Further studies are necessary to define the taxonomic status of strains regarded as either A. faecalis or "A. denitrificans" and with DNA base compositions of about 64 to 65 mol% G+C (7, 17).

A single-linkage dendrogram given by Seiler (19) shows 25 diagnostic characteristics out of 146 to be different among "A. denitrificans" DSM 30026T and the other two A. faecalis strains, DSM 30030T and DSM 30033T. However, the author did not mention which characteristics were different. The distinctive characteris-

tics found by Pichinoty et al. (17) for "A. denitrificans" DSM 30026T and A. faecalis DSM 30030T are listed after the description of "A. denitrificans" at the end of this paper.

Leifson and Hugh (11) described "A. denitrificans" NCTC 8582T as the type strain of a new species that reduced nitrate to nitrite and gas. According to Hendrie et al. (9), anaerobic respiration in the presence of nitrate in "A. denitrificans" NCTC 8582T may be lost on subculturing. This has been misinterpreted to mean that deni-

f Growth was used to measure assimilation of nitrate or nitrite.
trification is an unstable characteristic and therefore not useful for differentiating "A. denitrificans" NCTC 8582T from A. faecalis. The strain was isolated before 1954 (11) and has been kept aerobically in our culture collection since 1978, and it is still able to denitrify. Stanier et al. (22) discussed the significance of denitrification and concluded that the ability to use nitrate instead of oxygen as a terminal electron acceptor is a characteristic of considerable taxonomic value among pseudomonads.

We found that the ability to denitrify is dependent on the composition of the test medium (see Table 1) and, for strain DSM 30026T, upon the initial nitrate concentration. Strain DSM 30026T is able to denitrify in ASM + NH₄⁺ + NO₃⁻ and in ASM + NO₃⁻ containing 0.5 g of nitrate per liter. The 1.0 g or 5.0 g of nitrate per liter in ASM + NH₄⁺ + NO₃⁻ or in the mineral medium of Pichinoty et al. (17) affected the growth of strain DSM 30026T and, therefore, gas production was absent.

As shown in Table 1, "A. denitrificans" DSM 30026T also reduces nitrate to nitrite in the medium containing NH₄⁺. Therefore, a dissimilatory nitrate reductase is produced because assimilatory nitrate reductase is repressed by ammonium ion (3). The synthesis of assimilatory nitrate reductase in DSM 30026T cannot be proved by this method. According to Pichinoty et al. (17), nitrate reductase A, presumably a dissimilatory nitrate reductase, is produced by strain ATCC 15173T (=DSM 30026T). A. faecalis DSM 30030T did not reduce nitrate to nitrite in ASM + NH₄⁺ + NO₃⁻ and in ASM + NO₃⁻, and consequently both nitrate reductases are absent. The presence of an assimilatory nitrate reductase would cause growth of the cells and production of nitrite as an intermediate. These results are in agreement with those reported by Pichinoty et al. (17).

"A. denitrificans" DSM 30026T did assimilate nitrate (see Table 1). Surprisingly, Pichinoty et al. (17) reported "A. denitrificans" ATCC 15173T (=DSM 30026T) and five strains belonging to their "A. odorans" group as organisms not able to assimilate nitrate. However, Pichinoty et al. used 5.0 g of KNO₃ per liter in their medium.

"A. denitrificans" DSM 30026T assimilates nitrite and produces gas in ASM + NO₂⁻ and, therefore, an assimilatory and a dissimilatory nitrite reductase (3) are present. A dissimilatory nitrite reductase in strain DSM 30026T has been reported (17). A. faecalis DSM 30030T did not assimilate nitrate or nitrite, but gas was produced in ASM + NH₄⁺ + NO₃⁻, indicating that only a dissimilatory nitrite reductase was present (cf. Pichinoty et al. [17]). Preliminary tests revealed that the three strains investigated failed to grow in the ASM medium containing a KNO₂ concentration of 1.0 g/liter, whereas considerable growth occurred with 0.5 g of KNO₂ per liter. Therefore, this concentration was chosen for determining nitrite reduction to gas.

The agreement of nitrate reduction to nitrite, nitrite reduction to gas, and nitrite reduction to gas test results with those reported by Pichinoty et al. (17) demonstrates the reliability of these tests. The results are reproducible, but a mineral medium must be used. Sneath and Collins (21) reported the unreliability of nitrate reduction and denitrification tests, but their results were obtained with media containing peptone. Many bacterial strains produce ammonium ion from peptone, but ammonium ion is known to repress the assimilatory enzymes involved in nitrate or nitrite reduction (3).

The results presented in Table 1 and the DNA homology data confirm the combination of "A. odorans" with A. faecalis. The type strain of "A. denitrificans," however, cannot be united with A. faecalis. It is also not possible to transfer strain DSM 30026T to one of the other Alcaligenes species with G+C contents of about 68 mol% because A. eutrophus, A. latus, A. paradoxus, and A. ruhlandii are autotrophic organisms, and A. pacificus requires seawater medium for growth, utilizes glucose and fructose, and is not able to denitrify. Moreover, the name "A. denitrificans," published in 1954, would have priority over the other names, which were proposed between 1955 and 1978. Therefore, the species name Alcaligenes denitrificans is here revived.

**Description of A. denitrificans sp. nov. nom. rev., based on the type strain, NCTC 8582T.** The cells are gram-negative, short rods with rounded ends and occur singly, in pairs, or short chains. The average size is 0.7 to 1.0 μm by 1.2 to 3.0 μm as measured by phase-contrast microscopy. The cells are motile and peritrichious.

**Morphological characteristics:** colonies on agar are circular with an entire margin, flat, smooth, nonpigmented, translucent, and 1 to 2 mm in diameter. Good growth occurs in nutrient broth with uniform turbidity.

**Physiological growth characteristics:** aerobic, but capable of anaerobic respiration in the presence of nitrate or nitrite. The cells are mesophilic; growth occurs at temperatures between 10 and 37°C, and the optimal growth temperature is 24°C. The highest concentrations of NaCl permitting growth are 3.5 to 4.5%. Prototrophic.

Nitrate reduced to nitrite and gas. Gas produced from nitrite. Nitrate and nitrite, as sole sources of nitrogen, support growth.

Oxidase and catalase are produced. Indole, acetylacetic acid, hydrogen sulfide, and fluorescent pigment in King medium B are not
produced. Traces of ammonia are generated from peptone. Methyl red test is negative. No change in litmus milk.

Gelatin and casein are not digested. Urease, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, and extracellular DNase are not produced.

No acid from arabinose, fructose, glucose, glycerol, lactose, maltose, mannitol, sucrose, or xylose within 42 days.

Lipid, chitin, starch, and alginate are not hydrolyzed.

D-Glucose, D-galactose, D-fructose, and D-mannose are not utilized as sole sources of carbon, but growth occurs with sodium acetate, sodium succinate, sodium glutamate, and citrate.

DNA base composition: 69.1 ± 0.3 mol% G+C (Tm estimation).

Pichinoty et al. (17) reported the following nutritional tests as positive for “A. denitrificans”: utilization of β-saccharate, adipate, pmelate, suberate, β-hydroxy-β-methylglutamate, meso-tartrate, azelate, and itaconate.

A yellow fluorescent pigment is produced in King medium B; ammonium, but neither nitrate nor nitrite is used as a sole source of nitrogen; nitrate is not reduced to nitrite and gas, but gas is produced from nitrite in mineral media containing ammonium. According to Pichinoty et al. (17), A. faecalis CIP 6080T (= DSM 30030T) did not utilize β-saccharate, adipate, pmelate, suberate, β-hydroxy-β-methylglutamate, meso-tartrate, azelate, and itaconate.
