Royal College of Surgeons of England, Dental Research Unit, West Hill, Downe, Orpington, Kent,1 and The London Hospital Medical College, Dental School, Department of Oral Microbiology, London, E1 2AD,2 United Kingdom

We propose the name Streptococcus macaee sp. nov. for gram-positive, catalase-negative streptococcal strains that were isolated from the dental plaque of monkeys (Macaca fascicularis). This organism is distinct from other oral streptococci in that it produces acid from mannitol and raffinose but not from inulin or dextrin. It is not able to grow in the presence of bacitracin and does not produce hydrogen peroxide or hydrolyze arginine, but esculin is hydrolyzed, and dextran is produced from sucrose. Streptococcus macaee sp. nov. possesses the serotype c antigen described by Bratthall, as do Streptococcus mutans and Streptococcus ferus; however, the protein profiles of whole-cell extracts subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis and differences in deoxyribonucleic acid composition demonstrate that the new isolates are distinct from the two other species that possess the serotype c antigen and from other mutans streptococci. The guanine-plus-cytosine content of S. macaee is 35 to 36 mol%. The type strain is strain 25-1 (- NCTC 11558).

During the course of studies into the ecology of streptococci in the dental plaque of monkeys (Macaca fascicularis), we isolated organisms that differ from any previously reported species. These streptococci are mutants streptococci in that they produce acid from mannitol, form dextran from sucrose, and have the teeth as their major oral habitat (5). The biochemical and genetic differences between the new isolates and previously described mutans streptococcal species lead us to propose that the new strains represent a distinct species.

MATERIALS AND METHODS

**Bacterial strains.** The strains used in this study are listed in Table 1.

**Methods of characterization.** The phenotypic reactions of strains were studied by using media and methods which we have described previously (1). Additionally, we incorporated into our conventional identification system a test for acid production from dextrin which Kral and Daneo-Moore (12) found, using a miniaturized system, enabled differentiation of Streptococcus ferus from Streptococcus mutans. We found that S. ferus strains HD3 and 8SI (T = type strain) gave the same results in our test system as previously reported (12).

**Determination of DNA base composition.** To determine deoxyribonucleic acid (DNA) base composition, approximately 2 g (wet weight) of bacteria were lysed and treated by the method of Garvie (9) up to the step involving incubation with ribonuclease (final concentration, 50 μg/ml; type XIV; Sigma Chemical Co.), and incubation was continued for an additional 60 min. The solution was deproteinized by shaking with an equal volume of chloroform-octanol (24:1) and then centrifuged at 5,000 rpm for 10 min, and the upper aqueous layer was passed through a column (1 by 10 cm) of Sepharose 4B that was irrigated with standard saline citrate (0.15 M NaCl plus 0.015 M trisodium citrate, pH 7.0) at a flow rate of 0.1 ml/min (10). Fractions (2 ml) were collected, and the fraction corresponding to the first peak eluted from the column (determined by absorbance readings at 260 nm) was used to determine the guanine-plus-cytosine (G+C) content of the DNA. The thermal melting point of each DNA sample was determined in triplicate with a Gilford model 240 spectrophotometer at 260 nm by using a Gilford model 2527 thermopropgrammer with a heating rate of 1°C/min. DNAs isolated from S. mutans strain NCTC 10449T and Streptococcus rattus strain FA-1T were used for reference.

**Intraoral distribution.** Plaque samples from the developmental grooves of premolar teeth and tongue swablings were taken from eight monkeys and treated as previously described (1) in order to isolate streptococci.

**Serological procedures.** Antisera were raised by giving rabbits multiple injections of heat-killed bacteria as described by Bratthall (2). Immunodiffusion tests were performed by using glass slides coated with 1% (wt/vol) agarose in 0.5 M tris(hydroxymethyl)aminomethane hydrochloride buffer (pH 7.5). The sample wells were 4 mm in diameter and 4 mm apart and had a volume of 20 μl. Serotyping was performed by using the bacteria collected by centrifugation from 20 ml of a Todd-Hewitt broth (Oxoid Ltd.) culture as antigen (1).

**Polysaccharide antigen extraction.** Polysaccharides were prepared by hot phenol extraction of lyophilized cells (21). For purification of antigen, the polysaccharide preparation was applied to a column of diethylaminoethyl-Trisacryl M (LKB products Ltd.) in 0.5 M tris(hydroxymethyl)aminomethane hydrochloride buffer (pH 7.5). The column was eluted with a gradient of increasing concentrations of NaCl. The antigen contents of the eluted fractions were monitored by immunodiffusion.

The sugar contents of the polysaccharides were determined by hydrolyzing samples in 3 M HCl for 3 h at 105°C, removing the acid by evaporation, and subjecting the hydrolysates to thin-layer chromatography (16).

**SDS-PAGE of cell extracts.** The polyacrylamide gel electrophoresis (PAGE) patterns of sodium dodecyl sulfate (SDS) extracts of the new isolates were compared with the patterns of the other mutants streptococci by using previously described methods (1, 19).

**RESULTS AND DISCUSSION**

The 10 monkey isolates examined were gram-positive cocci that grew in chains and were isolated primarily from...

<sup>a</sup> Serotypes a, b, c, d, and e are described by Bratthall (3), serotypes f and g are described by Perch et al. (17), and serotype h is described by Bright et al. (1).

<sup>b</sup> With two exceptions, the S. mutans, S. sobrinus, S. cricetus, and S. ratus strains were obtained from J. M. Hardie, London Hospital Medical College, London, United Kingdom; S. mutans strain Ingbritt was obtained from G. Colman, and S. sobrinus strain MFe28 was isolated in our laboratory. The S. ferus strains were obtained from A. L. Coykendall, and all of the S. macacae strains were isolated in our laboratory.

dentition rather than tongues. They produced acid from mannitol and dextrin from sucrose but were unable to form \( \text{H}_2\text{O}_2 \) or grow in the presence of 6.5% NaCl. These are characteristics of mutans streptococci (5). These isolates were similar to two previously described species, S. mutans and S. ferus, in that they possessed the serotype c antigen described by Bratthall (3); the composition of the antigen also resembled the composition of the antigen of S. mutans (15, 22). However, an examination of the biochemical and physiological characteristics of the new isolates by using the scheme of Kral and Danco-Moore (12) showed that they differed from S. mutans in their inability to grow in the presence of bacitracin. They differed from S. ferus in that they produced acid from raffinose but failed to produce acid from dextrin or starch. Other differences were also apparent as the new isolates were able to produce acid from inulin, whereas both S. mutans and S. ferus did so, and only S. ferus produced acid from glycogen.

Data obtained with SDS-PAGE extracts of the mutants streptococci (1, 19) have supported the proposal of Coykendall (5) for the establishment of distinct species within this heterogeneous group of oral streptococci. The protein profiles obtained with SDS-PAGE of the serotype c-bearing strains have demonstrated the distinctness of S. ferus and S. mutans, and this supports our proposal that the new monkey isolates represent a distinct species.

The composition of the DNAs from the monkey isolates indicated a mean G+C content of 35 to 36 mol%, whereas the G+C content of S. mutans is 36 to 38 mol% and that of S. ferus is 42 to 44 mol%. Although we have not performed DNA homology studies, the differences in the DNA compositions indicate the separateness of the three groups of streptococci that possess the serotype c polysaccharide antigen.

We conclude that the monkey strains are different from other mutans streptococci and represent a new species, for which we propose the name *Streptococcus macacae* sp. nov. (macacae. M.L. fem.n. Macaca genus name of macaque; M.L. gen.n. macacae of macaque). The type strain is strain 25-1 (= NCTC 11558).

<sup>a</sup> Data from references 4 and 7.

<sup>b</sup> Data from references 1, 3, and 17.

<sup>c</sup> Data from reference 11.

<sup>d</sup> Data from reference 12.

<sup>e</sup> ND. Not determined.

<sup>f</sup> Serotype h strains produce acid from inulin, are not resistant to bacitracin, and do not produce H<sub>2</sub>O<sub>2</sub> (1).
in Todd-Hewitt broth and on sucrose-containing solid medium. The strains grow poorly in air, but growth is stimulated by the presence of CO₂; hence, growth occurs in candle jars and in anaerobe jars fitted with cold Deoxy catalyst (Oxoid) in an atmosphere initially consisting of 90% (vol/vol) H₂ and 10% (vol/vol) CO₂.

On sucrose-containing medium the colonies are easily removed but coherent. They are transparent and 1 to 2 mm in diameter after 3 days of incubation. As with other mutants streptococci (8), a less frequent colony form is produced, which is vivid white, less than 1 mm in diameter, erose, crumbly, and easily removed from the medium with a loop. Thetransparent forms always give rise to the two colony removed but coherent. They are transparent and 1 to 2 mm in diameter after 3 days of incubation. The transparent forms always give rise to the two colony types, but the vivid white forms retain their original colonial morphology despite repeated streaking onto fresh medium. Strains produce greening of horse blood agar plates whether they are grown anaerobically or in candle jars.

Biochemical characteristics. The strains examined all give similar results in the tests which we performed. Acid is produced from N-acetyl glucosamine, amygdalin, cellobiose, fructose, glucose, galactose, maltose, sucrose, and trehalose; sorbitol is fermented slowly. The terminal pH in sucrose broth varies from 4.6 to 4.9. No acid is produced from adonitol, arabinose, glycerol, inositol, melezitose, melibiose, ribose, sorbose, xylitol, or xylose. Additional characteristics are shown in Table 2. Dextran is produced from sucrose, and catalase is not produced; H₂O₂ is not produced. Growth occurs in media containing 10 and 40% (wt/vol) bile but not in the presence of 6.5% (wt/vol) NaCl, at 45°C, or at pH 9.6. Esculin is hydrolyzed; starch and blue dextran are weakly hydrolyzed, and arginine is not hydrolyzed.

Serotype c antigen. The strains of S. mutans, S. macacae, and S. ferus all contain an antigen which forms a precipitin line of identity when a bacterial pellet one of the strains is tested in an immunodiffusion assay with typing sera raised against S. mutans (three different sera) or strain 25-1T (Fig. 1). No other precipitin lines are observed with a wide range of antiserum concentrations and varying amounts of bacterial pellet. This antigen can be extracted from the bacteria by the Lancefield (14), Rantz-Randall (18), and hot phenol-water (21) procedures and has been purified by ion-exchange chromatography on diethylaminoethyl-Trisacryl. The serotype c antigen elutes at approximately 0.1 M NaCl. Glucose and rhamnose are the major sugars detected after hydrolysis of the antigen, as previously found for S. mutans (15, 22), although a trace of galactose also is found.

DNA composition. The G+C contents of three of the new isolates (strains H1569, H1762, and 25-1T) are 35 and 36 mol%, respectively. The values found for S. mutans NCTC 10449T and S. ratus Fitzgerald FA1T are 37 and 42 mol%, respectively; these values are almost identical to the values found by other workers (5).

Intraoral distribution. The strains of S. macacae were isolated primarily from dental plaque samples, indicating that tooth surfaces are the preferred habitat of these organisms (Table 3).

SDS-PAGE of cell extracts. The SDS-PAGE profiles of the 11 strains of S. macacae were identical and were distinct from the profiles of the other Streptococcus species examined. Figure 2 shows only the difference between the three streptococcal species bearing the serotype c polysaccharide antigen, as these species may be confused if serotyping is used to identify isolates. S. macacae, S. mutans, and S.

![FIG. 2. SDS-PAGE patterns of strains of S. mutans serotype c, S. macacae, and S. ferus. Lane 1, Molecular weight standards; lanes 2 through 5, S. mutans serotype c strain Ingbritt, strain NCTC 10449T, and two fresh monkey isolates, respectively; lanes 6 through 9, S. macacae strains 25-1T, B1107, 653, and H1569, respectively; lanes 10 and 11, S. ferus strains HD3 and 8St1T, respectively.](image-url)
ferus each has a characteristic protein profile that is distinctly different from the profiles of all other mutans streptococci.
