Amended Description of the Genus *Kineosporia*, Based on Chemotaxonomic and Morphological Studies

TAKASHI ITOH,†† TAKUJI KUDO,† FRANCESCO PARENTI,‡ AND AKIO SEINO†

*Japan Collection of Microorganisms, RIKEN, Wako-shi, Saitama 351-01, Japan,† and Lepetit Research Center, Gerenzano, Italy‡*

The description of the genus *Kineosporiu* is amended after chemotaxonomic and morphological studies of the type strain of the type species, *Kineosporiu aurantiaca* JCM 3230. This organism yielded both LL- and meso-diaminopimelic acid (A, pm) in the cell walls and arabinose, galactose, and xylose in the whole organism. Pagani and Parenti emphasized the structure of the sporangium of their strain, compared with the sporangia of the other sporangium-forming actinomycetes, and consequently placed it in the new genus *Kineosporiu*.

Recently, Hasegawa et al. (4) reported that whole cells of *K. aurantiaca* contain two isomers of A,pm, the LL and meso forms, but lack arabinose and xylose. Our analyses agree with the analyses of these authors. In addition, we observed that the spores are catenated or form aggregately at the tips of the vegetative hyphae. Our data indicate that the strain representative of the genus *Kineosporiu* shows some similarity to the spore dome actinomycetes described by Willoughby and by Makkar and Cross. Therefore, the description of the genus *Kineosporiu* should be revised, and further studies on *K. aurantiaca* should be undertaken. We studied this organism to gain a better understanding of the taxonomy of the monospecific genus *Kineosporiu*.

**MATERIALS AND METHODS**

**Strain used, cultivation, and spore collection.** *K. aurantiaca* JCM 3230T (= JCC A-0320T = A10312 Pagani and Parenti†) (T = type strain) was cultivated in yeast extract-glucose broth containing 10 g of yeast extract (Difco Laboratories, Detroit, Mich.) and 10 g of glucose in 1,000 ml of distilled water (pH 7.2) at 28°C for 5 to 6 days and then harvested by centrifugation. The biomass consisted of mycelial mats and numerous zoospores; this preparation was designated whole cultured organism.

Spores were collected from a spread culture grown on a dilute yeast extract-starch agar plate containing 0.5 g of yeast extract (Daigo Eiyo, Osaka, Japan), 2.5 g of soluble starch, and 15 g of agar in 1,000 ml of distilled water (pH 7.3) at 25°C for 6 days. The spread culture was dipped in distilled water, and the surface was lightly scratched to promote the release of motile spores. The resulting spore suspension was passed through filter paper (no. 2; Toyo Roshi, Tokyo, Japan), and the spores in the filtrate were collected by centrifugation at 10,000 × g for 15 min. The precipitate of spores was designated the spore fraction. Light microscopic observation indicated that the filtrate was free from mycelia.

**Amino acid composition of cell walls and A,pm and sugar analyses.** Cell wall peptidoglycan was prepared and hydrolyzed as described by Kawamoto et al. (6), and its amino acid composition was determined by using an automatic amino acid analyzer (model 835; Hitachi Ltd., Tokyo, Japan). The isomers of A,pm and the whole-organism sugar pattern were examined by using the methods of Stanek and Roberts (14).

**Lipid analyses.** Phospholipids were extracted from lyophilized cells with chloroform-methanol (2:1, vol/vol), purified, and identified as described by Lechevalier et al. (7). In this procedure, menaquinones eluted with chloroform from the silica gel column were collected and partially purified by thin-layer chromatography, using a Merck Kieselgel 60F254 plate developed with n-hexane-diethyl ether (9:1, vol/vol). Menaquinone composition was determined by high-performance liquid chromatography as described by Tamaoka et al. (17). Methanol-isopropanol (2:1, vol/vol) was used as an eluent. Cellular fatty acid composition was determined by applying the methyl esters prepared by the methanolation method of Ikemoto et al. (5) to a gas-liquid chromatograph (model GC-7A; Shimadzu Corp., Kyoto, Japan) equipped with a OV-1 capillary column (0.24 mm by 50 m) at 200°C and a flame ionized detector. The carrier gas was nitrogen. Gas-liquid chromatograms were analyzed by using a Shimadzu model C-R4A chromatograph-data processor. Mycolic acid was detected as described by Toriyama et al. (19).

**Determination of deoxyribonucleic acid base composition.** Deoxyribonucleic acid base composition was determined by the phenol method of Saito and Miura (12).
Chemotaxonomic characteristics. The cell wall compositions, isomers of \( \text{A}_{\text{pm}} \), and whole-cell sugar patterns of the whole cultured organism and the spore fraction are shown in Table 1. The ratios of the contents of glutamic acid, alanine, and \( \text{A}_{\text{pm}} \) in the two peptidoglycans were similar to each other; however, the glycine content of the spore fraction was less than that of the whole cultured organism. The whole cultured organism contained L- and meso-\( \text{A}_{\text{pm}} \) in comparable amounts and ribose, mannose, glucose, and galactose. In contrast, the spore fraction contained meso-\( \text{A}_{\text{pm}} \), ribose, and glucose, while L,L-\( \text{A}_{\text{pm}} \) was not detected and mannose was present in small amounts. A large amount of glucose in the spore fraction prevented the detection of galactose on the thin-layer chromatogram.

\( ^a \) Molar ratios, calculated by defining the amount of glutamic acid as 1.0.

\( ^b \) Cells, including mycelial mats and numerous zoospores, were collected from a liquid culture.

\( ^c \) Spores were collected from a spread culture cultivated on an agar plate.

\( ^d \) Galactose could not be detected due to the tailing of glucose on the thin-layer chromatogram.

Morphological properties. The following morphological characteristics of the organism agreed with those of the original description: colonies on oatmeal agar were orange with a glossy appearance, lacked aerial mycelia, and formed central projections having a conical crateriform shape; numerous zoospores were released from the surfaces of colonies immersed in water; single spores were attached to the ends of vegetative hyphae at the edges of colonies (Fig. 1); and a sheath was present surrounding the spores. Under scanning electron microscopic observation, a gelatinous matrix was separated from the colony surface, and the central projections seemed to show hyphae radiating toward the surfaces (Fig. 2). In addition, we observed catenated spores around the central projections. Although most of the colonies on water agar formed the central projections with radiating vegetative hyphae, some colonies had small dome projections that bore a number of spore clusters with sporophores, which were bunched together in the agar (Fig. 3). A spore cluster observed on oatmeal agar is shown in Fig. 4. The zoospores released from the surfaces of colonies bore polar tufts of flagella (Fig. 5).

DISCUSSION

\textit{K. aurantiaca} was first described as an actinomycte having cell wall type I containing glycine and L,L-\( \text{A}_{\text{pm}} \) (8), and its whole cell sugar pattern was peculiar because of the presence of arabinose, galactose, and xylose. However, in this study we demonstrated that this organism yields two isomers of \( \text{A}_{\text{pm}} \) without a characteristic sugar pattern (8), as reported by iasegawa et al. (4).

The whole cultured organism contained the two \( \text{A}_{\text{pm}} \) isomers, and the spore fraction contained only meso-\( \text{A}_{\text{pm}} \). Furthermore, the glycine content of the purified peptidoglycan of the spore fraction was less than that of the whole cultured organism. These data suggest that the mycelium peptidoglycan contains glycine and L,L-\( \text{A}_{\text{pm}} \), while the spore peptidoglycan contains meso-\( \text{A}_{\text{pm}} \). We presume that the previous data on this cell wall component depended on the analysis of a culture yielding few spores, possibly due to the medium composition and the incubation time (Emerson medium and 72 h of incubation). Although the sugar composition is changeable, at least in the mannose content, the detection of arabinose and xylose described in the original paper is not accounted for by the distribution of the sugars and mycelium in the preparation. We could not find any good reasons for the discrepancy.

A spore enclosed by a thin outer sheath was called a sporangium by Pagani and Parenti (11), who compared this structure with the sporangia of the other sporangium-forming actinomyces. Although such a morphological comparison is effective for identification of the organism, the term sporangium as applied to actinomyces is not well
defined, as pointed out by Williams et al. (22), and even actinomycetes with spore chains (e.g., Streptomyces spp.) bear spore sheaths. Furthermore, sporangium-forming actinomycetes are heterogeneous with respect to chemical data (3); the genera Microellobosporia, Elytrosporangium, and Kitasatoa have wall chemotype I, the genera Actinoplanes and Dactylosporangium and their relatives have chemotype IID, and the genera Streptosporangium, Planobispora, and Planomonospora have chemotype IIIB. Therefore, the organisms should be compared for their chemotaxonomic properties, as well with the properties of the other actinomycete genera.

*K. aurantiaca* had both LL- and meso-\(\Delta_2\)pm in its cell walls, lacked a characteristic sugar pattern, had phosphatidylcholine as a diagnostic phospholipid (type PIII), had MK-9(H4) as a main isoprenolog, and had a fatty acid profile lacking any iso/anteiso branched fatty acids. The two \(\Delta_2\)pm isomers are found in the walls of several Actinomadura (10), Micromonospora (6), and Kitasatosporia species strains (15, 16). The distribution of the \(\Delta_2\)pm isomers in *Kitasatosporia*...
species strains, which contain meso-A\textsubscript{2}pm in their mycelia and LL-A\textsubscript{2}pm in their spores (15, 16), is the reverse of the distribution of A\textsubscript{3}pm in \textit{K. aurantiaca}. The strains of \textit{Actinomadura} and \textit{Micromonospora} species have only a trace of

LL-A\textsubscript{3}pm, and it is not certain whether the occurrence of LL-A\textsubscript{3}pm is due to the presence of submerged spores in the preparation. Among the actinomycetes investigated so far (3), phosphatidylcholine and MK-9(\textsubscript{H}4) (as a main menaquinone component) have been found in some mycolateless wall chemotype IV actinomycetes (e. g., \textit{Faenia} and \textit{Saccharopolyspora} spp.), whereas a fatty acid profile lacking isosteres branched fatty acids is characteristic of mycolic acid-containing actinomycetes with cell wall type IV. Thus, the combination of the phospholipid, menaquinone, and fatty acid patterns of the test strain does not correspond to the pattern of any of known actinomycete genus. Grouping of aerobic actinomycetes based on cell wall amino acid composition and other chemotaxonomic properties reflects the phylogenetic relatedness deduced from 16S ribosomal ribonucleic acid data (3, 13). The chemotaxonomic properties of \textit{K. aurantiaca} might support a new line in the suprageneric classification of actinomycetes; however, the precise assignment of the genus \textit{Kineosporia} at the suprageneric level should await further appropriate approaches.

In this study we revised the chemotaxonomic and morphological properties of \textit{K. aurantiaca}, and our results support the contention that strain JCM 3230\textsuperscript{T} constitutes a valid genus. However, it should be noted that the morphology of \textit{K. aurantiaca} is quite similar to the morphologies of spore dome and spore head colonies described by Willoughby (23); the central (dome) projection and the spores occurring on an inflated phialidelike structure are termed spore dome and spore head, respectively. Makkar and Cross (9) also isolated the spore dome actinomycetes, which contained the two A\textsubscript{3}pm isomers, lacked a characteristic sugar pattern, and had MK-9(\textsubscript{H}4) as a main isoprenolog (1, 2, 9). Thus, the situation of the spore dome actinomycetes matches that of \textit{K. aurantiaca} in chemotaxonomic and the morphological aspects. It is interesting that the spore dome actinomycetes of Willoughby and of Makkar and Cross were isolated from freshwater habitats, whereas \textit{K. aurantiaca}...
was isolated from soil. Cross and Alderson have used the provisional name "Cupolomycetes" for the spore dome actinomycetes (1); however, these organisms could be accommodated within the genus Kineosporia. Preliminary numerical studies by Cross and Makkar (2) showed the heterogeneity within the spore dome actinomycetes, but further studies are needed to clarify the taxonomic status of K. aurantiaca and the spore dome actinomycetes.

At present, K. aurantiaca is the sole member of the genus, and the description of the genus Kineosporia is emended below.

Amended description of the genus Kineosporia Pagani and Parenti 1978. Aerobic, gram positive, and non-acid fast. Colonies on agar medium lack aerial mycelia, form central projections with radiating vegetative hyphae, and are occasionally accompanied by bunches of spore clusters in the agar. Mature colonies have a gelatinous matrix which confers a glossy appearance. Spores, which are spherical to oval, or pyriform with a long axis of 1 to 2 μm, are catenated around the central projection or are located singly or aggregated at the tips of hyphae. The spores are motile with polar tufts of flagella.

The peptidoglycan contains both LL- and meso-A4pm; the former, accompanied by glycin, is in the mycelium, and the latter is in the spores. The whole cultured organism contains galactose, glucose, mannose, and ribose, but the content of mannose is negligible in the spore fraction. Phosphatidyldcholine is a diagnostic phospholipid, and MK-9(H4) is present as a main menaquinone component. The cellular fatty acid profile mainly contains 16:0, 18:1, and 10Me 19:0, and lacks iso/anteiso branched fatty acids. 2-Hydroxy fatty acids are also present. Lipid compositions are not significantly different in the whole cultured organism and the spore fraction. Mycolic acids are absent. The guanine-plus-cytosine content of the deoxyribonucleic acid is 69.2 mol%.

K. aurantiaca is the type species, and the type strain is strain JCM 3230 (= ATCC 29727).

FIG. 5. Transmission electron micrograph of a zoospore with a polar tuft of flagella. Bar = 1 μm.

ACKNOWLEDGMENT

We thank M. Chijimatsu, RIKEN, Saitama, Japan, for analyzing the amino acid composition of the peptidoglycans.
