*Thiobacillus thermosulfatus* ATCC 51520T (T = type strain) was isolated from sewage sludge samples enriched with elemental sulfur. The cells of this organism were gram negative, rod shaped, motile, facultatively autotrophic, and strictly aerobic and contained polyphosphate inclusions and polyhedral bodies. During growth on thiosulfate, the following intermediates were produced: tetrathionate, trithionate, and sulfate, and the pH was lowered from neutrality to around 2.5. Autotrophic growth was observed at pH values between 4.3 and 7.8 and at temperatures of 34 to 65°C; optimum growth occurred at pH 5.2 to 5.6 and 50 to 52.5°C. Ubiquinone Q8 was present in the respiratory chain. The DNA contained 61 ± 1 mol% G+C. No denitrification was observed under autotrophic and heterotrophic conditions. The cells produced a glycolcyclic during growth in the presence of SO4. As determined by a 16S rRNA gene sequence analysis, *T. thermosulfatus* is a distinct species that belongs to the beta subdivision of the *Proteobacteria* and is closely related phylogenetically to *Thiobacillus permutabilis*. The GenBank accession number for the complete 16S rRNA gene sequence of *T. thermosulfatus* is U27839.

According to Kelly and Harrison (17) in *Berger's Manual of Systematic Bacteriology*, the only criterion for grouping all of the *Thiobacillus* species in one genus is that all of these organisms are rod-shaped eubacteria that obtain energy for autotrophic growth from oxidizing inorganic sulfur-containing substrates. Consequently, this genus comprises species that have different pH, temperature, and nutrient requirements. In fact, it includes organisms that are acidiphilic, organisms that are neutrophilic, organisms that are thermophilic, denitrifiers, and facultative heterotrophs (19). When temperature requirements are considered, the following three *Thiobacillus* species are recognized as moderadamente thermophilic organisms: *Thiobacillus tepidarius*, *Thiobacillus aquaeulis*, and *Thiobacillus caldus* (33–35). A *Thiobacillus*-like moderately thermophilic bacterium was also partially characterized by Williams and Hoare (32).

The great phenotypic diversity of the thiobacilli is supported by the results of genetic analyses. The first phylogenetic study of sulfur- and iron-oxidizing eubacteria placed members of the genus *Thiobacillus* in three of the four subdivisions of the *Proteobacteria* (21, 27). A phylogenetic analysis of 16S rRNA gene sequences revealed that most members of the genus *Thiobacillus* belong to the beta subdivision, but some strains were recognized as members of the gamma subdivision. Recently, isolates were described as members of a new genus, and *Thiobacillus* sp. nov. (24, 25). In this paper we describe the isolation and the genotypic and phenotypic characteristics of this new thermophilic colorless sulfur bacterium, *Thiobacillus thermosulfatus* sp. nov.

**MATERIALS AND METHODS**

Isolation and cultivation of *Thiobacillus thermosulfatus*. Sludge samples obtained from municipal wastewater treatment plants were amended with 0.5% (wt/vol) tyndallized S8 powder and incubated in shaking water bath at 53°C. Samples were removed aseptically daily to measure the decrease in pH. Aliquots were transferred into medium A, which contained (per liter) 2.04 g of KH2PO4, 0.2 g of (NH4)2SO4, 0.2 g of CaCl2?2H2O, 0.5 g of MgSO4?7H2O, and 0.02 g of bromophenol blue (pH adjusted to 0.0), and S8 powder was added. After a few transfers, the S8 was replaced by 20 mM sodium thiosulfate. Typically, the pH decreased from 6.0 to 2.3 to 2.5 in less than 24 h. Serial dilutions were spread onto medium A supplemented with 20 mM thiosulfate and 0.6% (wt/vol) Gelrite (22), and the preparations were incubated at 50°C for 2 days. Elimination of heterotrophic sporulated bacteria was verified throughout the isolation process on medium H (which contained 1.0 g of glucose per liter, 5.0 g of tryptone per liter, 2.5 g of yeast extract per liter, 0.6% Gelrite, and 0.57 g of CaCl2?2H2O per liter) since growth of *Thiobacillus thermosulfatus* was never observed on this medium. Because all of the strains which we isolated were identical in terms of the rate of pH decrease, the minimum pH attained, and colonial and cellular morphology, one isolate was chosen arbitrarily for further characterization.

**Determination of pH and temperature for growth.** Experiments to determine the pH and temperature for growth were performed by using medium A supplemented with 20 mM thiosulfate. The pH was automatically controlled with a pH controller (Horizon Ecology Co.). Growth was monitored by measuring the optical density at 400 nm by using a 30-ml cuvette with 10-cm optical path. The specific growth rate constant (k) was determined from the expression $k = \ln2(t_2 - t_1)$, where $(t_2 - t_1)$ was the time interval required for the bacterial count to double during the exponential growth phase.

<sup>a</sup> Levels of similarity were calculated by excluding insertions and deletions and were based on 850 nucleotide positions (see Materials and Methods).

<sup>b</sup> Data from reference 21.

<sup>c</sup> This organism was used as an outgroup in phylogenetic analyses.

<sup>d</sup> This strain is the type strain of a group of closely related isolates ATCC 19377, ATCC 19859, ATCC 23270, B-53, IFO 14245, and IFO 14262 (Fig. 4).

<sup>e</sup> The level of similarity was 95.4% when all of the available sites were included in a pairwise comparison (see Results).

<sup>f</sup> Previously named *Thiobacillus thysiares* (36).

<sup>g</sup> Previously named *Thiobacillus versutus* (13).

**Growth on sulfur compounds and organic compounds.** Growth experiments were performed at 50°C by using medium A supplemented with thiosulfate (20 mM), tetrathionate (10 mM), thioate (5, 17, and 85 mM), S<sup>0</sup> (0.5%), or the following organic substrates: acetate (20 mM), aspartate (10 mM), glucose (10 mM), succinate (10 mM), sucrose (10 mM), sorbitol (10 mM), xylose (10 mM), and yeast extract (0.05%). In order to determine whether the turbidity that developed resulted from contaminating heterotrophic bacteria, growth was monitored by determining viable cell counts on both solid medium A and solid medium H.

**Formation of intermediate products.** Formation of tetrathionate and trithionate during growth on sodium thiosulfate and elemental sulfur was monitored by determining turbidity (using cyanolysis (16)). Sulfate production was determined by measuring turbidity (using DNA from *Thiobacillus* thermosulfatus) or by inductively coupled plasma atomic emission spectroscopy.

**Anaerobic growth.** Whether nitrate was used as an electron acceptor in the absence of oxygen was determined under anaerobic and heterotrophic conditions by using medium A supplemented with thiosulfate (20 mM) or yeast extract (0.05%). Medium A was supplemented with 33 mM KNO<sub>3</sub> and 25 mM NaHCO<sub>3</sub>.

**Microscopy.** Thin layers were cut with a Reichert model OM V2 diamond microtome, placed on type 200HH copper grids, and stained with uranyl acetate and lead hydroxide. The grids were examined with a Philips model EM 300 electron microscope.

**16S rRNA gene sequencing and analysis.** DNA was extracted as described by Beji et al. (1). The 16S rRNA gene was amplified by PCR. The primers used for DNA amplification were primers SSU 27 (3), SSU 536 (GTGCCAGCMGCCGCGTAATAC), SSU 701 (AAACTYAAAGKGAATTGACGG), and SSU 1195 (GAGGAAGGTGGGATGACGTC) for the 3' and 5' DNA strands, and primer SSU 1942 (3) for the 5' and 3' DNA strands. DNA amplification was performed with a Perkin-Elmer Cetus model 480 cycler. The temperature profile was as follows: initial denaturation at 94°C for 3 min, followed by 30 cycles consisting of 94°C for 1 min, 53°C for 1 min, and 73°C for 1.5 min. The final extension step consisted of 73°C for 10 min. PCR products were purified by spin column chromatography (PCR purification kit; Qiagen, Chatworth, Calif.) and were sequenced directly by using an ABI model 373 automated sequencer and a Tag DyeDeoxy cycle sequencing kit (Perkin Elmer-ABI, Foster City, Calif.). The sequence which we obtained was aligned with 20 other 16S rRNA gene sequences (see Fig. 4 for taxonomy names) by using the PILEUP program of the University of Wisconsin Genetic Computer Group (7), and the alignment was completed manually. GenBank accession numbers for the other 16S rRNA sequences which we used were L01478, L01479, M34113, M79396 to M79398, M79401 to M79432, M90662, X07839, X75269, and 229975. Desulfovibrio desulfuricans was used as an outgroup for rooting purposes. Ambiguous regions were removed, and the resulting alignment of 850 nucleotides (corresponding to positions 201 to 413, 441 to 476, 591 to 863, and 1019 to 1339 of the 16S rRNA gene of *Thiobacillus thermosulfatans*) was used for phylogenetic analyses.

A standard parsimony analysis was performed by using the branch-and-bound search algorithm of PAUP version 3.1.29. Minimal gaps were considered missing values. One-parameter (12) and two-parameter (18) substitution rates, which also took into account transitions and transversions, were estimated from pairwise levels of sequence similarity by using MEGA, version 1.0 (20). The pairwise sequence deletion option was used, and gaps were considered missing values. The resulting matrices of substitution rates which were estimated by a bootstrap procedure (10) in which we used 10 replicates for
RESULTS

Isolation of Thiobacillus thermosulfatus. Initially, colonies on solid medium A were composed of Thiobacillus thermosulfatus and gram-positive sporeformers; the latter were subsequently identified as members of a thermophilic Bacillus species. After 10 subcultures on medium A, the sporeformers disappeared. When a colony from a solid medium A culture was transferred to solid medium H, no growth of the thiobacilli or sporeformers was observed after incubation for 15 days at 50°C. Thus, the heterotrophic sporeformers were eliminated from the Thiobacillus thermosulfatus colonies on medium A. Other gelling agents were used with medium A supplemented with thiosulfate. Only 2% purified agar (BBL) gave results similar to the results obtained with Gelrite. With 2% Bacto Agar (Difco), growth was slower than the growth obtained with Gelrite, and it took more than 8 days to detect acid production when it was detected at all. The relationship between dilutions on Bacto Agar and colony counts was also poor. Neither growth nor acid production was observed on medium containing 1% agarose (Sigma) after incubation for 15 days.

Growth conditions. A decrease in the viable cell counts on solid medium A occurred after 5 h if the pH was less than 3.6. At pH 4.4, 5.0, 6.8, and 7.8, the amount of biomass increased slightly; at these pH values, growth was observed only when the plate count method was used. At pH 5.8 and 6.5, growth was observed by the turbidity and plate count methods. During pH-controlled experiments, the maximum specific growth rate was obtained at pH values between 5.2 (0.180 h⁻¹) and 5.6 (0.182 h⁻¹) and at temperatures between 50.0°C (0.180 h⁻¹) and 52.5°C (0.173 h⁻¹). Growth occurred on media containing thiosulfate, tetrathionate, and elemental sulfur. Growth did not occur on medium containing thiocyanate under the conditions tested. During growth on thiosulfate, tetrathionate, tri- and sulfate were produced (Fig. 1). Heterotrophic growth occurred on media containing yeast extract, glutamate, and succinate. Characteristic odor was noticed at the end of growth on organic and inorganic substrates; this odor may have been due to the excretion of organic compounds, as has been shown for Thiobacillus aquaesulis (35). Under anaerobic conditions, no growth occurred under autotrophic and heterotrophic conditions. Tetrathionate and triionate were not produced from thiosulfate, and the pH remained stable. Under both autotrophic and heterotrophic conditions, no nitrite resulting from reduction of nitrate was observed.

Microscopy. An electron micrograph (Fig. 2) revealed that a single polar flagellum, polyhedral bodies, and polyphosphate inclusions were present in each cell. Scanning electron microscopy (Fig. 3) revealed that an extensive glycocalyx was produced during growth on S² tablets. The filamentous appearance of the glycocalyx was probably the result of the dehydration procedure used during sample preparation (28). Cells intimately associated with the glycocalyx can be seen in Fig. 3. Typically, two or three polyphosphate inclusions per cell were visible when Loeffer's staining procedure was used. The dimensions of the cells during exponential growth were 1.3 to 2.3 by 0.9 μm. There were two cells per chain, and the Gram reaction was negative.

G+C and ubiquinone contents. The average G+C content was 61 ± 1 mol%. The ratio of optical density at 260 nm to optical density at 280 nm was more than 1.76 in all cases, indicating that the samples which we used were clean. The Rs values for ubiquinone Q8 (extracted from Escherichia coli) and ubiquinone Q10 were 0.86 and 0.69, respectively. The Rs value for the ubiquinone extracted from Thiobacillus thermosulfatus was 0.87, and this ubiquinone was formally identified as ubiquinone Q8. Addition of ubiquinone Q10 to a Thiobacillus thermosulfatus extraction preparation resulted in two different spots with Rs values of 0.86 and 0.70, corresponding to ubiquinones Q8 and Q10, respectively.

Phylogenetic analysis. The topologies estimated from the standard parsimony analysis and the neighbor-joining analyses of one-parameter and two-parameter substitution rates were essentially the same. The two neighbor-joining trees were identical and differences with the most parsimonious tree were observed only for the nodes that were not supported by bootstrap estimates of 50% or more, which are shown as polytomies on the neighbor-joining tree derived from the analysis of one-parameter substitution rates (Fig. 4); this tree summarizes the phylogenetic relationships among the Thiobacillus species, including the relationships based on the recently determined 16S rRNA gene sequences of Thiobacillus caldus, Thiobacillus hydrothermalis, Thiobacillus thermosulfatus, and Thiobacillus ferroxidans B-S3. The 16S rRNA gene sequence of thiobacillus strain NF13 (GenBank accession numbers M79387, M79388, and M79389) was intentionally omitted from the phylogenetic analyses because only 456 nucleotides of this sequence have been determined and only 249 of these 456 nucleotides could be used in the final alignment; thus, the number of sites available for a balanced analysis of all other taxa would have been reduced, and this would have decreased the precision of the estimated trees. Nevertheless, when such an analysis was performed, strain NF13 occurred with Thiomicrospira thysasi (previously named Thiobacillus thysaris) with a neighbor-join-
ing bootstrap value of 58%. It follows that thiobacillus strain NF13 should not be considered a *Thiobacillus* species.

The newly isolated organism, *Thiobacillus thermosulfatus*, was placed in the beta subdivision and beta-1 subgroup of the Proteobacteria because of its relationship with *Thiobacillus perometabolis*, which was previously placed in this subgroup (21). In fact, the highest level of sequence similarity for *Thiobacillus thermosulfatus* was the level of sequence similarity obtained with *Thiobacillus perometabolis* (96.5%, obtained from the sequence alignment used to infer phylogenetic trees) (Table 1). When we took into account all of the sequence information available for *Thiobacillus thermosulfatus* and *Thiobacillus perometabolis*, including the information for regions deleted from the phylogenetic analyses because of alignment ambiguities between remote taxa, the level of similarity was 95.4%. We obtained low levels of sequence similarity between *Thiobacillus thermosulfatus* and the two other thermophilic thiobacilli, *Thiobacillus caldus* (80.2%) and *Thiobacillus tepidanus* (80.9%). Our phylogenetic analysis also revealed that the moderately thermostable acidophilic organism *Thiobacillus caldus* is closely related to *Thiobacillus ferrooxidans* LM2, a facultative thermophile. The strictly autotrophic mesophilic organism *Thiobacillus hydrothermalis* was found to be closely related to *Thiobacillus neapolitanus*, which is also a strictly autotrophic mesophilic organism. The newly sequenced organism *Thiobacillus thiooxidans* B-S3 belonged to the beta subdivision and was closely related to the cluster containing almost all of the *Thiobacillus ferrooxidans* and *Thiobacillus thiooxidans* strains, as recently shown by Goebel and Stackebrandt (11). As found in previous studies (11, 21), our phylogenetic tree confirmed that the genus *Thiobacillus* is heterogeneous and polyphyletic and thus is not a natural group.

**DISCUSSION**

The newly isolated organism *Thiobacillus thermosulfatus* is phenotypically quite different from all of the other *Thiobacillus* species that have been isolated except the thiobacillus described by Williams and Hoare (32). The isolate of Williams and Hoare had optimum pH and temperature values similar to those of *Thiobacillus thermosulfatus* and was able to produce enough sulfuric acid from thiosulfate to increase the level of acidity to approximately pH 2.6, like *Thiobacillus thermosulfatus*. The only difference between these two organisms was the difference in their G+C contents (66 mol% for strain of Williams and Hoare, compared with 61 mol% for *Thiobacillus thermosulfatus*). Unfortunately, the isolate of Williams and Hoare has not been deposited in any type culture collection, and so additional comparisons could not be performed. *Thiobacillus tepidanus* and *Thiobacillus aquaesulis* are also phenotypically similar to *Thiobacillus thermosulfatus*. Unfortunately, both organisms have not been deposited in any type culture collection, and so additional comparisons could not be performed. *Thiobacillus tepidanus* and *Thiobacillus aquaesulis* are also phenotypically similar to *Thiobacillus thermosulfatus*. While *Thiobacillus thermosulfatus* has an optimum temperature (50 to 52°C) that is different from the optimum temperatures of *Thiobacillus tepidanus* and *Thiobacillus aquaesulis* (43 to 45°C and around 43°C, respectively [33, 35]), *Thiobacillus thermosulfatus* is facultatively chemolithoautotrophic on yeast extract, like...
**Fig. 3.** Scanning electron micrograph of glycocalyx production during growth on elemental sulfur.

*Thiobacillus aquaesulis*, but it can also grow on glutamate and succinate. The optimum pH for *Thiobacillus tepidarius* is 6.0 to 7.5, and the optimum pH for *Thiobacillus aquaesulis* is around 7.6, whereas the optimum pH for *Thiobacillus thermosulfatus* is between 5.2 and 5.6. The G+C content of *Thiobacillus thermosulfatus* (61 mol%) is slightly different from the G+C contents of *Thiobacillus tepidarius* (66.6 mol%) and *Thiobacillus aquaesulis* (65.7 mol%). Autotrophic growth of *Thiobacillus thermosulfatus* under optimum conditions decreased the pH from neutrality to around 2.5, a phenomenon which was not observed during growth of *Thiobacillus tepidarius* and *Thiobacillus aquaesulis* under optimum conditions. *Thiobacillus thermosulfatus* does not appear to be phenotypically related to the genus *Thermothrix* (5) because of its inability to denitrify and grow under anaerobic conditions.

The results of phylogenetic analyses of 16S rRNA gene sequences indicated that *Thiobacillus thermosulfatus* is related to *Thiobacillus perometabolis* and *Thiobacillus thioparus*, which is the type species of the genus *Thiobacillus* (17). However, the levels of 16S rRNA sequence similarity between *Thiobacillus thermosulfatus* and these organisms are less than the limit (97%) used to define distinct species at the DNA level without the requirement for DNA-DNA reassociation tests (26). Furthermore, *Thiobacillus thermosulfatus* is phenotypically quite different from these strains. It cannot denitrify and grow under anaerobic conditions and is not a mesophilic obligate autotroph like *Thiobacillus thioparus* (19). *Thiobacillus thermosulfatus* has an optimum growth temperature (50 to 52°C) that is greater than the maximum growth temperature for *Thiobacillus perometabolis* (42°C) (14, 15). The G+C content of *Thiobacillus thermosulfatus* (61 mol%) is also different from the G+C content of *Thiobacillus perometabolis* (65 mol%). In addition, heterotrophic growth of *Thiobacillus perometabolis* on glutamate and succinate begins after a long lag phase (about 2 weeks) (15), which was not observed during heterotrophic growth of *Thiobacillus thermosulfatus* on these substrates. Because *Thiobacillus thermosulfatus* has at least two differentiating phenotypic characteristics and a divergent 16S rRNA sequence, it can be considered a new species (26, 31).

We believe that reassociation experiments involving *Thiobacillus thermosulfatus* and *Thiobacillus perometabolis* DNAs were not necessary because the level of 16S rRNA sequence similarity (95.4%) was below the critical value of 97% (26). Indeed, according to Stackebrandt and Geobel (26), “organisms that have less than 97.0% sequence homology will not reassociate to more than 60%, no matter which hybridization method is applied.” The phylogenetic position of *Thiobacillus thermosulfatus*, together with the reclassification of *Thiobacillus versutus* and *Thiobacillus thyasiris* as *Paracoccus versutus* (13) and *Thiomicrospira thyasirae* (9, 36), respectively, and the close relationship between *Thiobacillus acidophilus* and the genus *Acidiphilium* suggest that the genus *Thiobacillus* is more restricted than previously thought; most *Thiobacillus* strains belong to the beta subdivision of the Proteobacteria.

From an ecological point of view, bioproduction of sulfate at 50°C in the presence of elemental sulfur was observed not only in sludge samples obtained from municipal wastewater treatment plants but also in soil samples and sludge samples ob-
autotrophically on thiosulfate, tetrathionate, and sulfur and heterotrophically on yeast extract, succinate, and glutamate. *Thiobacillus thermosulfatus* does not grow on carbohydrates, pyruvate, acetate, or formate. When thiosulfate is used as the primary energy source, tetrathionate, trithionate, and sulfate are produced. During growth on elemental sulfur and thiosulfate, the pH decreases from neutrality to around pH 2.5. During elemental sulfur oxidation, a considerable amount of sulfate (up to 6,000 mg/liter) is produced, depending on the pH-buffering capacity of the medium. The cells adhere to elemental sulfur by means of a glyocalyx, as judged by the extensive production of a glyocalyx during growth on this substrate. Autotrophic growth on thiosulfate occurs between pH 4.3 and 7.8 and at temperatures of 34 to 65°C; optimum growth occurs at pH 5.2 to 5.6 and 50 to 52.5°C. Ubiquinone Q8 is present in the respiratory chain. The G+C content of the DNA is 61 ± 1 mol%. No denitrification occurs under autotrophic and heterotrophic conditions. As determined by a 16S rRNA gene sequence analysis, *Thiobacillus thermosulfatus* belongs to the beta subdivision of the Proteobacteria and is closely related phylogenetically to *Thiobacillus perometabolis* and *Thiobacillus thioparus*. Its 16S rRNA sequence is most similar to the 16S rRNA sequence of *Thiobacillus perometabolis* (level of similarity, 95.4%). The GenBank accession number for the complete 16S rRNA gene sequence of *Thiobacillus thermosulfatus* is U72839.

**ACKNOWLEDGMENTS**

We thank D. P. Kelly, R. Guay, J.-C. Auclair, and T. R. Sreekrishnan for reading a draft of the manuscript and providing useful suggestions. We also thank J.-F. Blais for suggestions during the bacterial isolation procedure, E. Emond for the early tentative sequencing and help during PCR amplification, L. Simon and J. Renaud for assistance with automated gene sequencing, and A. Roy for help with the phylogenetic analyses.

We thank Fonds pour la Formation de Chercheurs et l'Aide à la Recherche of Quebec and the Natural Sciences and Engineering Research Council of Canada (grants A9494, STR 0100710, and STR 149770) for supporting this research.
