A strain of a thermophilic, anaerobic, dissimilatory, Fe(III)-reducing bacterium, Thermoterrabacterium ferrireducens gen. nov., sp. nov. (type strain JWAS-Y7T; DSM 11255), was isolated from hot springs in Yellowstone National Park and New Zealand. The gram-positive-staining cells occurred singly or in pairs as straight to slightly curved rods, 0.3 to 0.4 by 1.6 to 2.7 μm, with rounded ends and exhibited a tumbling motility. Spores were not observed. The temperature range for growth was 50 to 74°C with an optimum at 65°C. The pH range for growth at 65°C was from 5.5 to 7.6, with an optimum at 6.0 to 6.2. The organism coupled the oxidation of glycerol to reduction of amorphous Fe(III) oxide or Fe(III) citrate as an electron acceptor. In the presence as well as in the absence of Fe(III) and in the presence of CO2, glycerol was metabolized by incomplete oxidation to acetate as the only organic metabolic product; no H2 was produced during growth. The organism utilized glycerol, lactate, 1,2-propanediol, glycerate, pyruvate, glucose, fructose, mannose, and yeast extract as substrates. In the presence of Fe(III) the bacterium utilized molecular hydrogen. The organism reduced 9,10-anthraquinone-2,6-disulfonic acid, fumarate (to succinate), and thiosulfate (to elemental sulfur) but did not reduce MnO2, nitrate, sulfate, sulfite, or elemental sulfur. The G+C content of the DNA was 41 mol% (as determined by high-performance liquid chromatography). The 16S ribosomal DNA sequence analysis placed the isolated strain as a member of a new genus within the gram-type-positive *Bacillus-Clostridium* subphylum.

The use of Fe(III) as an electron acceptor by microorganisms has important environmental implications and may be associated with the evolution of microbial life (19, 25). Microorganisms which couple the oxidation of organic compounds with Fe(III) reduction are phylogenetically diverse, including members of the gamma and delta subclasses of Proteobacteria and gram-positive organisms (18), and may be subdivided into two physiological groups: those that completely oxidize multi-carbon compounds to carbon dioxide and those that incompletely oxidize organic substances to acetate. The first group includes *Geobacter* (5, 20), *Desulfurimonas* (7), *Desulfuromusa* (18), and *Geovibrio* (6) species, while the second group includes *Shewanella* (4, 27, 29), *Pelobacter* (22), *Ferrimonas* (28), and *Bacillus* (2) species.

Microbial Fe(III) reduction has been intensively studied in mesobiotic marine and freshwater anoxic sediments and submerged soils (21), but little is presently known about microbial reduction of Fe(III) in thermobiotic ecosystems. Some geological evidence from iron oxide deposits is suggestive of Fe(III)-reducing thermophile activity (13, 14). Ferric iron reduction coupled to oxidation of acetate or molecular hydrogen has been described for microbial consortia of thermophilic microorganisms from different geothermal areas (30, 31). Thermophilic Fe(III) reducers available in pure culture so far include only the aerobic archaeon *Sulfolobus acidocaldarius*, which reduces ferro iron with elemental sulfur (3), and the obligately anaerobic *Bacillus infernus*, which is able to reduce Fe(III) with formate and lactate at temperatures between 40 and 65°C (2). In this paper we describe an anaerobic, dissimilatory, Fe(III)-reducing (eu)bacterial thermophile, *Thermoterrabacterium ferrireducens* gen. nov., sp. nov., which belongs to the Gram-type-positive *Bacillus-Clostridium* subphylum and which has been isolated from hot springs in Yellowstone National Park.

**MATERIALS AND METHODS**

**Environmental samples.** Mixed samples of sediment, water, and black and white stringy biomass were collected in September 1995 from several sites at Calcite Springs Yellowstone National Park in Wyoming. The temperatures at the sampling sites ranged from 40 to 85°C, and the pH ranged from 6.0 to 8.3. Media and cultivation. A basal medium used for enrichment, isolation, and cultivation of Fe(III)-reducing bacteria was prepared by the modified Hungate technique (17) under a CO2 (100%) gas phase. The basal medium contained (per liter of deionized water) 0.33 g of KH2PO4, 0.33 g of NH4Cl, 0.33 g of KCl, 0.33 g of MgCl2·6H2O, 0.33 g of CaCl2·2H2O, 2.0 g of NaHCO3, 3.0 ml of glycerol, 10 ml of vitamin solution (39), and 1 ml of trace element solution. The basal element solution contained (per liter) 2.0 mmol of (NH4)2Fe(SO4)2·6H2O, 2.0 mmol of Na2SO4, 1.0 mmol of CoCl2·6H2O, 1.0 mmol of NiCl2·6H2O, 0.5 mmol of MnCl2·4H2O, 0.5 mmol of ZnSO4·7H2O, 0.5 mmol of Na2SeO3·5H2O, 0.1 mmol of Na2MoO4·2H2O, 0.1 mmol of Na2WO4·2H2O, 0.1 mmol of H3BO3, and 0.01 mmol of CuCl2·2H2O. The pH was adjusted to 7.0 at 25°C (pH25°) with 10% (wt/vol) NaOH. No reducing agent was added to the medium. Fe(III) was provided in the form of amorphous Fe(III) oxide at ca. 90 mmol of Fe(III) per liter of medium. The amorphous Fe(III) oxide was synthesized by titrating a solution of FeCl3 with 10% (wt/vol) NaOH to pH 9.0. The pH25° of the autoclaved medium was 6.8 to 6.9.

Unless otherwise noted, enrichment and pure cultures were grown in 10 ml of medium in Hungate tubes under an atmosphere of CO2 (100%). All transfers and samplings of the cultures were performed with syringes and needles. The medium was heat sterilized at 135°C for 30 min. All incubations were at 65°C unless otherwise noted.

**Determination of growth.** Growth of bacteria in medium containing amorphous Fe(III) oxide or other insoluble compounds was determined by direct counting with a phase-contrast microscope and a Neubauer chamber (Hauser Scientific Partnership, Horsham, Pa.). In media with soluble compounds, growth was determined by counting and by measuring the increase in optical density at 600 nm (OD600) (Spectronic 21; Bausch & Lomb, Rochester, N.Y.).

Temperature, pH, and NaCl concentration ranges. Temperature ranges for growth and Fe(III) reduction were determined in basal medium by using a temperature gradient incubator (Scientific Industries, Inc., Bohemia, N.Y.) with shaking (15 strokes per min). The pH range for growth was determined at 65°C. The basal medium was modified by omitting amorphous Fe(III) oxide and adding yeast extract (5 g/liter), fumarate (20 mM), and either morpholinethanesulfonic acid (MES) or HEPES (10 mM; NaOH [100%]) was used as the gas phase. The pH was adjusted with sterile stock solutions of HCl or NaOH at 65°C and measured with a model 815 MP pH meter (Fisher Scientific, Pittsburgh, Pa.) equipped with a temperature probe and calibrated at 65°C. The effect of NaCl on growth and Fe(III) reduction was determined in basal media containing 0, 0.5, 1.0, 1.5, and 2.0% (wt/vol) NaCl.

Substrate utilization. The ability of the organism to grow on different substrates was determined in basal medium in which the glycerol was replaced by autoclaved or filter-sterilized substrates, both in the presence and in the absence of amorphous Fe(III) oxide. When Fe(III) was omitted, the medium was prereduced with Na$_2$S·9H$_2$O (0.5 g/liter). The potential for molecular hydrogen to serve as an electron donor was studied in 60-ml flasks containing 10 ml of medium and with H$_2$, CO$_2$ (80:20 or 5%--5% [vol/vol]) as the gas phase. In experiments with elemental sulfur, basal medium was supplemented with acetate (5 g/liter) and yeast extract (0.5 g/liter) as carbon sources and elemental sulfur (150 mM). The cultures were incubated for 2 weeks, and substrate utilization was monitored by measuring growth, Fe(II) accumulation, or acetate production. A medium in which the organic carbon source had been omitted was used as a control.

Electron acceptors. The potential use of different electron acceptors was studied in the basal medium containing glycerol (30 mM) as a sole electron donor but lacking amorphous Fe(III) oxide. The different electron acceptors were added from autoclaved stock solutions. The medium was prereduced with Na$_2$S·9H$_2$O (0.5 g/liter) in the experiments with sulfate, sulfite, thiosulfate, elemental sulfur, and fumarate. No reducing agent was present in media containing O$_2$, Fe(III) citrate, MnO$_2$, or 9,10-anthraquinone-2,6-disulfonic acid. Both reduced and reducing-agent-free media were used in nitrate-amended experiments. Cultures grown with glycerol in prereduced basal medium without an electron acceptor were used as inocula (10% [vol/vol]). The use of the electron acceptors was monitored by measuring growth (for all acceptors), by sulfide production (for sulfate, sulfite, thiosulfate, and elemental sulfur), by high-performance liquid chromatography (HPLC [for fumarate]), and by measuring changes in the visible color of the medium or precipitate (for Fe(III) citrate, MnO$_2$, 9,10-anthraquinone-2,6-disulfonic acid, and thiosulfate).

Antibiotic susceptibility. Susceptibility to antibiotics was determined by transferring an exponentially growing culture into fresh basal medium containing 100 μg of filter-sterilized antibiotic per ml. The cultures were incubated at 50°C for 2 weeks.

Microscopy. Routine examinations and cell counting were performed with a light microscope (model PM 10 AD [Olympus Optical Co., Ltd., Tokyo, Japan]) equipped with phase-contrast optics. Transmission electron microscopy was performed with a model JEM-100 CXII electron microscope (JEOL, Tokyo, Japan). The samples used for ultrathin sectioning were prepared by postfixation with uranyl acetate and lead citrate as described by Spurr (32). Gram staining was performed by the method of Hucker as described by Doetsch (10).

Analytical techniques. Fe(III) reduction was monitored by measuring the accumulation of Fe(II) over time. Fe(II) was measured by adding a 0.5-mm sample from the culture to 5 ml of 0.6 N HCl. After 24 h of extraction, HCl-soluble Fe(II) was determined with 2,2′-dipyridyl (1). Sulfide was determined by a modification of a method of Cord-Ruwisch (8). Determining the concentration of glycerol, short-chain organic acids, and alcohols was performed by HPLC as previously described (33). Molecular hydrogen was analyzed by gas chromatography (33).

G+C content of DNA. The DNA was isolated and purified by the NaOH method of Mesbah et al. (24). The DNA was digested enzymatically, and the guanine-plus-cytosine (G+C) content was determined by separating the nucleotides by HPLC as described by Whitman et al. (36) and Mesbah et al. (24).

Extraction and sequencing of DNA and analysis of 16S rRNA genes. The genomic DNA was extracted from cell pellets by standard methods (23). The 16S ribosomal DNA (16S rDNA) was amplified by PCR as described previously (11). The double-stranded PCR products were sequenced by cycle sequencing with an ABI 373 automated sequencer. The 16S rDNA sequences were aligned manually with a representative set of 16S rDNA sequences obtained from the Ribosomal Database Project or from recent GenBank releases. The secondary structure was used as a guide to ensure that only homologous regions were compared. A total of 1,503 nucleotides were sequenced, and 1,202 were used in the phylogenetic analysis. The absence of chimeric molecules was ensured by using the secondary structure and computer analyses. The phylogenetic trees were constructed either with evolutionary distance matrices, using the algorithm of De Soete (9), with maximum-likelihood analysis, using the program fastDNAml (26). Bootstrap values were obtained for maximum-likelihood analysis by using 100 replicates treated as random addition of sequence.

Nucleotide sequence accession number. The 16S rDNA sequence of strain JW/AS-Y7T has been deposited in GenBank under accession number U76363.

FIG. 1. Phase-contrast light micrograph showing the cell morphology of strain JW/AS-Y7T. Growth was on basal medium with 9,10-anthraquinone-2,6-disulfonic acid as an electron acceptor. Bar = 5 μm.

RESULTS

Enrichment and isolation. Eleven samples obtained from thermal areas in Yellowstone National Park were used for enrichment of thermophilic dissimilatory Fe(III)-reducing microorganisms (see Materials and Methods). Basal anaerobic medium, in which glycerol was a potential electron donor and amorphous Fe(III) oxide was provided as an electron acceptor, was inoculated with 10% (wt/vol) of the sample and incubated at 60 and 65°C in the dark. After 48 to 72 h of cultivation, in four enrichments from Calceite Springs samples, nonmagnetic brown amorphous Fe(III) oxide was converted to a black solid material of less volume which was strongly attracted to a magnet and contained a significant amount of Fe(II). For the isolation of a pure culture, the enrichment with the fastest rate of Fe(III) reduction (sampling point, 72°C; pH 7.0, 7.5) was chosen. After three successive 10% (wt/vol) transfers, the enrichment was repeatedly serially diluted to extinction in the basal medium. The high concentration that was positive for Fe(III) reduction (10⁻⁹) was serially diluted to extinction in agar shake tubes (1.5% Bacto Agar) in the glycerol-containing basal medium in which Fe(III) oxide was omitted and Na$_2$S·9H$_2$O (0.5 g/liter) was provided as a reducing agent. Single colonies were removed and subcultured in liquid medium with glycerol and amorphous Fe(III) oxide. This process was repeated twice, after which the culture was considered to be pure and was designated as strain JW/AS-Y7T. Some other, similar Fe-reducing strains with similar morphology were isolated. Their taxonomic positions and physiology are under further investigation.

Colony and cell morphology. In agar shake cultures, colonies appeared after 2 to 3 days. The colonies were uniformly round, 0.5 to 0.8 mm in diameter, and nonpigmented. The cells of strain JW/AS-Y7T were straight to slightly curved rods, 0.3 to 0.4 μm in diameter and 1.6 to 2.7 μm in length, with rounded ends (Fig. 1). The cells occurred singly or in pairs and exhibited a tumbling motility. The formation of spores was not observed.
FIG. 2. Electron micrographs from ultrathin sections of cells of strain JW/AS-Y7T. Growth was on basal medium with amorphous Fe(II) oxide as an electron acceptor. (a) The cells are elongated rods covered by a layer of very electron-dense particulate material (FE). (b) The electron-dense particulate material (FP) appears to be precipitated on the outside of an electron-transparent wall layer (IW); CM, cytoplasmic membrane. (c) Electron-dense material (arrowheads) is not only present at the cell surface but is also detached from the cells. The three groups of two arrows each point to electron-dense material which appears to have the shape of platelets or needles. (d) Cells in a state of plasmolysis. Although the cytoplasmic membrane (CM) is retracted from the wall, the electron-dense material, together with the wall layers, forms a shell-like structure (FE). (e) Sections through the pole of a cell with only very minor amounts of electron-dense material (three arrows). The cell envelope is composed of the cytoplasmic membrane (CM), an electron-transparent inner wall layer (IW) which may have been artificially formed by partial plasmolysis, an electron-dense layer (PG) most probably made up of peptidoglycan, an electron-transparent outer wall layer (OW1), and an electron-dense outermost wall layer (OW2). Note that formation of the electron-dense particulate material begins in OW1. Small arrowheads point to regularly arranged intensity maxima, indicating the presence of an S layer. N, nucleoid.
Gram staining reaction, Gram type, and cell wall analysis. The cells stained gram positive in both the exponential and stationary growth phases. The cell wall structure of strain JW/AS-Y7T (Fig. 2e) and the absence of a positive reaction in the lipopolysaccharide-polymyxin B assay of Wiegel and Quandt (38) are consistent with it being a Gram-type-positive organism (37). This is in agreement with the 16s rRNA sequencing data which placed the organism in the *Clostridium-Bacillus* subphylum.

The ultrathin sectioning of strain JW/AS-Y7T grown in the medium with amorphous Fe(III) oxide revealed that a prominent feature of the cells is the presence of dark deposits on the outside of the cell wall (Fig. 2a to e). Electron energy loss spectroscopy analysis confirmed the presence of iron in these deposits.

Temperature, pH, and NaCl concentration ranges. The temperature range for growth of strain JW/AS-Y7T was 50 to 74°C, with an optimum at 65°C (Fig. 3). No growth and no Fe(III) reduction were detected at 76°C or lower after 3 weeks of incubation; Strain JW/AS-Y7T grew in a range from pH 5.5 to pH 7.6, with an optimum at pH 6.0 to 6.2 (Fig. 4). No growth was detected at pH 5.3 or at pH 7.8. Growth and Fe(III) reduction of JW/AS-Y7T was observed at NaCl concentrations ranging from 0 to 1.0% (wt/vol), with no growth evident at 1.5% (wt/vol).

Growth and Fe(III) reduction. In the presence of CO₂, strain JW/AS-Y7T grew anaerobically with glycerol as the only organic carbon source (Fig. 5). When amorphous Fe(III) oxide or Fe(III) citrate was present in the medium, the strain coupled the oxidation of glycerol to the reduction of Fe(III). The cell numbers increased with the consumption of glycerol and the concomitant accumulation of Fe(II). Without an external electron acceptor, growth was weaker, and the maximal cell density did not exceed 2 × 10⁸ cells/ml (OD₆₀₀ = 0.06). Addition of 0.05% yeast extract did not significantly stimulate the growth of strain JW/AS-Y7T.

Glycerol was oxidized incompletely to acetate in the absence as well as in the presence of Fe(III). No H₂, CH₄, C₂ to C₃ alcohols, diols, or organic acids, except acetate, were detected in the cultures at any growth stage. In the presence of CO₂, the ratio of acetate produced to glycerol consumed was 1.28 ± 0.3 (mean ± standard deviation for five cultures) for strain JW/AS-Y7T in cultures with amorphous Fe(III) oxide or Fe(III) citrate (growth, 6.3 × 10⁸ cells/ml) and 1.69 ± 0.3 (mean ± standard deviation for five cultures) in cultures without Fe(III) (growth, 2.0 × 10⁸ cells/ml). With amorphous Fe(III) oxide or Fe(III) citrate as an electron acceptor, the ratio of Fe(II) produced to glycerol consumed was 1.02 ± 0.4 (mean ± standard deviation for five cultures).

Substrate utilization. The substrates utilized by strain JW/AS-Y7T in the presence as well as in the absence of Fe(III) as an electron acceptor included glycerol (40 mM), lactate (20 mM), 1,2-propanediol (20 mM), glycerate (20 mM), pyruvate (20 mM), and yeast extract (5 g/liter). Fe(III) significantly stimulates growth of the strain with all substrates utilized. Poor (change in optical density of 0.04 to 0.05 compared to the control with no added carbon source) but still viable growth was observed in the medium without Fe(III) supplemented with 25 mM glucose, fructose, or mannose; the consumption of carbohydrates did not exceed 1 mM, and the only organic metabolic product formed was acetate. Fe(III) was chemically reduced by carbohydrates in sterile controls. Thus, the test for carbohydrate utilization in the presence of Fe(III) is equivocal. In the presence of amorphous Fe(III) oxide or 9,10-anthraqui-
none-2,6-disulfonic acid, strain JW/AS-Y7T grew on H₂-CO₂ (80:20 or 5:95% [vol/vol]) and utilized molecular hydrogen. Without external electron acceptors, growth on H₂-CO₂ and net consumption of H₂ were not observed.

Strain JW/AS-Y7T did not utilize formate (20 mM), acetate (30 mM), methanol (20 mM), ethanol (20 mM), n-propanol (20 mM), i-propanol (20 mM), n-butanol (20 mM), propionate (20 mM), acetone (20 mM), ethylene glycol (20 mM), 1,3-propanediol (20 mM), fumarate (20 mM), succinate (20 mM), phenol (10 mM), benzol (20 mM), 9,10-anthraquinone-2,6-disulfonic acid (20 mM), starch (5 g/liter), olive oil (10 ml/liter), precipitated S₀ (150 mM), sublimated S₀ (150 mM), sucrose (25 mM), galactose (25 mM), xylose (25 mM), cellobiose (25 mM), or arabinose (25 mM) with or without Fe(II) as an electron acceptor.

Electron acceptors. Strain JW/AS-Y7T coupled the oxidation of glycerol to reduction of amorphous Fe(III) oxide (90 mM), Fe(III) citrate (20 mM), fumarate (10 mM), thiosulfate (20 mM), and 9,10-anthraquinone-2,6-disulfonic acid (2.0 mM). Fumarate was reduced to succinate. Thiosulfate was reduced to elemental sulfur. Strain JW/AS-Y7T did not reduce nitrate (20 mM) or sulfate (20 mM), and precipitated S₀ (150 mM), sublimated S₀ (150 mM) with glycerol as an electron donor.

Antibiotic susceptibility. Chloramphenicol, erythromycin, and rifampicin completely inhibited growth and Fe(III) reduction at a concentration of 100 μg/ml of medium. Ampicillin, streptomycin, and tetracycline at 100 μg/ml did not inhibit growth and Fe(III) reduction.

DNA base composition. The G+C content of the genomic DNA of strain JW/AS-Y7T was 41 mol% (as determined by HPLC).

Phylogeny. 16S rDNA sequence analysis indicated that strain JW/AS-Y7T is a member of the Bacillus-Clostridium subphylum of the Gram-type-positive (eu)bacteria (Fig. 6). Phylogenetic trees based on maximum-likelihood analyses and distance matrices were similar. However, bootstrap values for the position of JW/AS-Y7T indicated that this position is not yet conclusively resolved. Isolation of closer relatives should help resolve this. Using the available 16S rRNA (or rDNA) sequences, similarity matrices generated by the Jukes and Cantor correction (16) as modified by Olsen (35) revealed that JW/AS-Y7T was 83% similar to Ammonifex degensii (15), the nearest neighbor.

DISCUSSION

Strain JW/AS-Y7T is a facultative Fe(III) reducer, capable of oxidizing organic substrates in the presence and absence of Fe(III). This strain represents the first dissimilatory Fe(III)-reducing anaerobic thermophile isolated from a terrestrial geothermal area and is the first example of direct isolation from a thermobiotic environment of an organism that uses Fe(III) as an electron acceptor. Greater cell numbers were obtained in media containing Fe(III), suggesting that Fe(II) reduction may play a role in energy conservation. The observation that no molecular hydrogen was produced during growth under all tested conditions suggests that Fe(III) reduction is not a detoxification process. While the pathway of glycerol degradation remains unknown, the results obtained do suggest that the isolated organism is an acetogenic bacterium. Based on the obtained stoichiometry, the degradation of glycerol could be described by equation 1, with reduction of CO₂ (12, 34), or by equation 2, with reduction of CO₂ and Fe(III).

\[ 4C₂H₄O₃ + 2HCO₃⁻ = 7C₂H₂O₄⁻ + 5H⁺ + 4H₂O \]  
\[ 8C₂H₄O₃ + 2HCO₃⁻ + 8Fe³⁺ = 13C₂H₂O₄⁻ + 19H⁺ + 4H₂O + 8Fe²⁺ \]
The process involving Fe(III) reduction gives a higher yield of energy per mole of glycerol consumed. The relatively high variability of experimental data on acetate/glycerol ratios suggests that the processes of CO₂ and Fe(III) reduction could be competitive, especially in a heterophase system with insoluble amorphous Fe(III) oxide.

The 16S rDNA sequence analysis places strain JW/AS-Y7T in the Gram-type-positive *Bacillus-Clostridium* subphylum and thus separates it from the members of the Gram-type-negative family *Geobacteraceae* and gamma proteobacteria that accommodate most of the mesophilic dissimilatory Fe(III) reducers. The capacity for dissimilatory Fe(III) reduction generally has not been tested among thermophilic anaerobes. So far, the only described (eu)bacterial anaerobic thermophile capable of dissimilatory Fe(III) reduction is *B. infernus*. Strain JW/AS-Y7T differs from *B. infernus* in morphology, temperature and pH ranges and optima, electron acceptors utilized, and products of glucose fermentation (Table 1). On the basis of physiological properties and phylogenetic analysis, we propose that strain JW/AS-Y7T represents a new species of a new genus.

**Description of *Thermoterrabacterium gen. nov., Thermoterrabacterium* (Ther.mo.ter.ra.bac.te'ri.um. Gr. adj. thermos, hot; L. n. terra, land, earth; Gr. neut. n. bacterion, a small rod; M. L. neut. n. *Thermoterrabacterium*, rod-shaped bacterium from heated land). Rod-shaped, Gram-type-positive (eu)bacteria. Anaerobic and thermophilic. Neutrophilic. Facultative Fe(II1) reducers. Facultative anaerobe converting to a different state; the members of the Gram-type-positive Bacillus-Clostridium subphylum. Rod-shaped, Gram-type-negative family *Geobacteraceae* and gamma proteobacteria that accommodate most of the mesophilic dissimilatory Fe(III) reducers. Facultative anaerobic thermophile capable of dissimilatory Fe(III) reduction is *B. infernus*. Strain JW/AS-Y7T differs from *B. infernus* in morphology, temperature and pH ranges and optima, electron acceptors utilized, and products of glucose fermentation (Table 1). On the basis of physiological properties and phylogenetic analysis, we propose that strain JW/AS-Y7T represents a new species of a new genus.

**Description of *Thermoterrabacterium ferrireducens* sp. nov., *Thermoterrabacterium ferrireducens* [fer.ri.re. du.cens. L.n. fer- rum, iron; L. part. adj. reducens, converting to a different state; M. L. adj. *ferrireducens*, reducing iron (III)]. Straight to slightly curved rods, 0.3 to 0.4 by 1.6 to 2.7 μm with rounded ends. Cells stain gram positive. Occurring singly or in pairs. Exhibits a tumbling motility. Spores were not observed. Anaerobic. Grows on simple, defined medium. The temperature range for growth is 50 to 74°C with the optimum being 65°C. The pH range for growth is 5.5 to 7.6, with an optimum at 6.0 to 6.2. Growth occurs in the NaCl concentration range of 0 to 1.0% (wt/vol). In the presence of CO₂, strain JW/AS-Y7T is able to grow with glycerol as the only organic carbon source. Couples the oxidation of glycerol to reduction of amorphous Fe(III) oxide or Fe(II1) citrate as an electron acceptor, forming Fe(II1) as magnetite and siderite. In the presence as well as in the absence of Fe(III), and in the presence of CO₂, glycerol is oxidized incompletely to acetate as the only organic metabolic product, leading to a ratio of more than one acetate molecule produced per glycerol molecule consumed. Does not produce H₂. Utilizes glycerol, lactate, 1,2-propanediol, glycerate, pyruvate, and yeast extract. Grows weakly on glucose, fructose, and mannose, producing acetate as the only organic product. In the presence of Fe(III) utilizes molecular hydrogen. No growth occurs with formate, acetate, methanol, ethanol, n-propanol, isopropanol, n-butanol, propionate, acetone, ethylene glycol, 1,3-propanediol, fumarate, succinate, phenol, benzene, 9,10-anthraquinone-2,6-disulfonic acid, starch, olive oil, elemental sulfur, sucrose, galactose, xylose, cellobiose, or arabinose, with or without Fe(III). Reduces 9,10-anthraquinone-2,6-disulfonic acid, fumarate to succinate, and thiosulfate to elemental sulfur. Does not reduce MnO₂, nitrate, sulfate, sulfite, or elemental sulfur. Growth is inhibited by chloramphenicol, erythromycin, and rifampin at 100 μg/ml but not by ampicillin, streptomycin, or tetracycline. DNA base composition is 41 mol% G+C (HPLC). The habitat is freshwater hot springs such as Calcite Springs in Yellowstone National Park, Wyoming.

The type strain and, so far, the only isolated strain is JW/AS-Y7T, which has been deposited with the Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH under accession number DSM 11255.
