Several yeast species/isolates belonging to the genus *Saccharomyces* were examined for the organization of their mtDNAs and ability to generate petite mutants. A general characteristic for all of the mtDNAs tested was that they were very A+T-rich. However, restriction patterns and inducibility of petite mutations revealed a great diversity in the organization and genetic behaviour of mtDNAs. One group of yeasts, *Saccharomyces sensu stricto*, contains mtDNA ranging in size from 64 to 85 kb. mtDNAs from these yeasts contain a high number of restriction sites that are recognized by the enzymes *Haelll* and *Mspl*, which cut specifically in G+C clusters. There are three to nine orihp sequences per genome. These yeasts spontaneously generate respiration deficient mutants. Ethidium bromide (Et-Br), at low concentrations, induces a majority of cells to give rise to petites. A second group of yeasts, *Saccharomyces sensu lato*, contains smaller mtDNAs, ranging in size from 23 to 48 kb, and probably only a few intergenic G+C clusters and no orihp sequences. These yeasts also generate petite clones spontaneously, but Et-Br, even when present at high concentrations, does not substantially increase the frequency of petites. In most petite clones from these yeasts only a small fragment of the wild-type molecule is retained and apparently multiplied. A third group, represented by *Saccharomyces kluyveri*, does not give rise to petite mutants either spontaneously or after induction.

**Keywords**: yeast, mitochondrial genome, petite mutation, intergenic sequences, taxonomy

**INTRODUCTION**

A remarkable aspect of mitochondrial genomes of all organisms is that they contain a very similar set of genes. On the other hand, mtDNA molecules among diverse species are highly variable in size and organization (5, 36). The yeast *Saccharomyces cerevisiae* has played the central role in studies of mtDNA heredity (for reviews, see 9, 28). This is due mainly to the property that this yeast is a facultative anaerobe; i.e. it can survive without active mitochondria. The average cell of *S. cerevisiae* contains as many as 50 mtDNA molecules, but the number varies with the genotype and physiological conditions (for a review, see 14). mtDNA of *S. cerevisiae* is characterized by a very low G + C content (18 mol %), and clustering of G + C- and A + T-rich regions (37). Most methods of preparation yielded exclusively linear molecules, but mapping and sequencing of the genome showed that the genetic map of mtDNA is circular (9). The ‘long’ version of the genome, containing additional introns and intergenic sequences, is 85 kb in size and the ‘short’ version is 74 kb (37). Genes represent less than one-fifth of the mtDNA molecule, the rest consists of introns and intergenic sequences. The intergenic regions represent about two-thirds of mtDNA and consist of repetitive A + T-rich spacers and short sequences with a G + C content greater than 50 mol %, so-called G + C clusters. Approximately 200 A + T spacers with a mean size of 190 bp represent

3 Carlsberg Research Laboratory, Denmark

†Present address: Department of Food Science and Technology, Biotechnical Faculty, University of Ljubljana, 1000 Ljubljana, Slovenia.
almost half of the genome, and they are usually separated from each other by over 200 G+C clusters (38). A large fraction of G+C clusters contains recognition sites for restriction enzymes splitting target sequences which contain only G and C residues, i.e. HaeIII and HpaII/MspI (38). A special class of G+C clusters are ori/rep sequences which are about 300 bp long and are present in eight copies scattered around the genome (4, 40). G+C clusters can be grouped into eight families which presumably originated from a proto-G+C cluster (38). Therefore, mtDNA contains a variety of short duplications which potentially can be involved in intramolecular recombination.

*S. cerevisiae* spontaneously produces mutants, petites, which are deficient in the ability to respire aerobically. The spontaneous frequency is about 1%, but upon induction with chemical mutagens, e.g. ethidium bromide (Et-Br), all cells may give rise to petites (for reviews, see 2, 13, 14). The petite phenotype is correlated with gross alterations, extensive deletions or loss of mtDNA (2). These deletions may be accompanied by reiteration of the remaining wild-type segments, so that some petite mutants contain the same amount of mtDNA as wild-type strains (2, 33). The sequences involved in excision of petite mtDNA are short direct repeats located in the A+T spacers and G+C clusters (8, 39). Therefore, the intergenic sequences are directly involved in destabilization of the mitochondrial genome. Once a petite mtDNA molecule is generated, it may gain exclusive representation in a daughter cell.

The majority of spontaneous petite mtDNA molecules exhibit a high transmission capacity in genetic crosses. In crosses with wild-type strains, such petites give a type strain and some additional isolates of all species. The strains carrying the CBS designation were obtained from the Centraal Bureau voor Schimmelcultures, Delft, The Netherlands. The NRRL strains originate from the National Center for Agricultural Utilization Research, Peoria, IL, USA. In addition, a laboratory strain of *S. cerevisiae*, T3/3 (10), was used as a standard in several experiments.

**mtDNA isolation.** For isolation of DNA, a culture was pregrown inYPD medium (2% glucose, 0.5% yeast extract, 1% peptone) and then grown overnight in GlyYP (2% glycerol, 0.5% yeast extract, 1% peptone) at 25°C. Spheroplasts were prepared using zymolyase and lysed with SDS. mtDNA was separated from the other DNA using a bisbenzimide-CsCl gradient (27). At least two bands appeared in the gradient and they were tested for cross-hybridization with the *S. cerevisiae* mitochondrial probes. When the bands were poorly resolved, the upper fraction was isolated and re-subjected to centrifugation in a CsCl gradient.

**DNA techniques.** mtDNA was digested with various restriction enzymes, and DNA fragments were separated by electrophoresis in 0.8–1.2% agarose gels. Lambda DNA digested with various restriction enzymes was used as the size marker. The size of mtDNA was calculated from several independent digestions using at least five different restriction enzymes. DNA was transferred from gels to Hybond-N+ (Amersham) membranes under alkaline conditions. Hybridization was performed at 55°C with radioactive mitochondrial probes.

Previously, it was not known whether the observations on the structure and genetic stability of mtDNA of *S. cerevisiae* could be extrapolated to other closely related yeasts. The genus *Saccharomyces* can be divided into two major groups: *sensu stricto* (including *S. cerevisiae*) and *sensu lato* (1, 20). In the present study the type strain and some additional isolates of all currently recognized species of the genus *Saccharomyces* were examined with regard to some characteristics of their mtDNA and their ability to generate petites. Apparently, at least three categories with differing organization and genetic stability of mtDNA exist in this genus. One has mtDNA larger than 64 kb, contains G+C clusters and is highly inducible for petite generation. The second category contains mtDNA molecules with fewer than 50 kb and is less inducible for petite generation. The third category is represented by a single petite-negative member.

**METHODS**

**Yeast strains.** The following *Saccharomyces* yeast type isolates were studied for their mtDNA molecules: *Saccharomyces bayanus* (CBS 380°), *Saccharomyces carlsbergensis* (CBS 1513°), *Saccharomyces castellii* (NRRL Y-12636°), *S. cerevisiae* (NRRL Y-12632°), *Saccharomyces dairiensis* (NRRL Y-12639°), *Saccharomyces douglasi* (CBS 2908), *Saccharomyces exiguis* (NRRL Y-12640°), *Saccharomyces kluveri* (NRRL Y-12651°), *Saccharomyces monacensis* (CBS 1503), *Saccharomyces paradoxus* (NRRL Y-17217°), *Saccharomyces pastorius* (CBS 1538), *Saccharomyces servazzii* (NRRL Y-12661°), *Saccharomyces unisporus* (NRRL Y-1556°), *Saccharomyces uvarum* (CBS 395). ‘T’ indicates a type strain, and represents a separate species, but some isolates, as will be shown below, apparently belong to the same species. The strains carrying the CBS designation were obtained from the Centraal Bureau voor Schimmelcultures, Delft, The Netherlands. The NRRL Y-strains originate from the National Center for Agricultural Utilization Research, Peoria, IL, USA. In addition, a laboratory strain of *S. cerevisiae*, T3/3 (10), was used as a standard in several experiments.

**mtDNA isolation.** For isolation of DNA, a culture was pregrown inYPD medium (2% glucose, 0.5% yeast extract, 1% peptone) and then grown overnight in GlyYP (2% glycerol, 0.5% yeast extract, 1% peptone) at 25°C. Spheroplasts were prepared using zymolyase and lysed with SDS. mtDNA was separated from the other DNA using a bisbenzimide-CsCl gradient (27). At least two bands appeared in the gradient and they were tested for cross-hybridization with the *S. cerevisiae* mitochondrial probes. When the bands were poorly resolved, the upper fraction was isolated and re-subjected to centrifugation in a CsCl gradient.

**DNA techniques.** mtDNA was digested with various restriction enzymes, and DNA fragments were separated by electrophoresis in 0.8–1.2% agarose gels. Lambda DNA digested with various restriction enzymes was used as the size marker. The size of mtDNA was calculated from several independent digestions using at least five different restriction enzymes. DNA was transferred from gels to Hybond-N+ (Amersham) membranes under alkaline conditions. Hybridization was performed at 55°C with radioactive probes prepared by the random priming method. The following probes were used: plasmids carrying *S. cerevisiae* mitochondrial *LrRNA* or *SrRNA* genes (obtained from H. Fukuhara, Orsay, France) and petite mtDNA carrying the *S. cerevisiae oril* sequence (3). These mitochondrial probes helped to distinguish mtDNA from other DNA bands present in the CsCl gradient.

**G + C content.** The G+C content of mtDNA was determined using CsCl buoyant density centrifugation. Pure mtDNA, isolated from a CsCl gradient was mixed with purified nuclear DNA from *S. cerevisiae* and run again in the ultracentrifuge. The G+C contents of non-*S. cerevisiae* mtDNAs were determined using *S. cerevisiae* nuclear (40 mol% G+C) and mtDNA (18 mol% G+C) as standards.
Mitochondrial genomes of \textit{Saccharomyces} yeasts

(37). It was assumed that the density of mtDNA in a band can be determined from a linear function of its distance from the bands of both standards (21). An error of this method has been estimated to be ±0.5 mol% of the G+C content.

**G+C Clusters.** If the sequence of nucleotides is completely random the number of sites for any particular restriction enzyme can be predicted. In the case of 'G+C-cutters', i.e., \textit{HaeIII} and \textit{MspI}/\textit{HpaII}, which contain four bases in the target site, the following equation can be used:

\[
\text{Number of sites} = \frac{\text{number of base pairs}}{(G+C \text{ content})/2}^4.
\]

However, in \textit{S. cerevisiae} a wide discrepancy between the observed and the predicted numbers of sites of \textit{HaeIII} and \textit{HpaII} (\textit{MspI}) exists, because of clustering of \textit{G} and \textit{C} residues.

**Spontaneous petite mutations.** The spontaneous frequency of petites was determined by plating yeast cultures on the medium containing a limiting amount of a fermentable carbon source. Yeasts pre-grown in YPD were diluted and plated on GGlyYP (2% glycerol, 0.1% glucose, 0.5% yeast extract, 1% peptone and 1.5% agar). After a few days of growth, the frequency of small colonies, putative petite mutants, was determined. These colonies were examined for growth on GlyYP and tested for respiratory potential using the tetrazolium method (22). mtDNA was isolated from some of the non-respiratory colonies and examined with several restriction enzymes.

**Induced petite mutations.** The induction of petites by treatment with Et-Br was studied. Various amounts of Et-Br were added to exponentially growing yeast cells in YPD, and growth was continued for an additional 8 h. During this period cells should normally divide three or four times. If a petite mutation was induced at the beginning of the treatment, it could have segregated into a homoplasmic clone by the end of the treatment. Heteroplasmic cells containing a mix of wild-type and petite mtDNA at the time of plating, would generate colonies which contained respiration-competent and -deficient cells. Such colonies would in part respire, and they would be scored as respiration-competent. Following the Et-Br treatment the cells were washed and plated on the GGlyYP medium. After several days the frequency of petites was determined.

**RESULTS AND DISCUSSION**

**mtDNA molecules vary in size**

When total DNA from different yeast isolates was separated on a CsCl gradient, at least two distinct bands appeared. The positions of these bands in the gradients varied slightly and, in addition, the distance between them was variable. The pattern with two bands resembled the pattern known in \textit{S. cerevisiae} where the upper band represents mtDNA and the lower one nuclear DNA (for a review, see 9). The upper band from various yeast isolates always gave a positive reaction when hybridized to the \textit{S. cerevisiae} mitochondrial gene probes. The lower band, which was stronger in intensity, did not hybridize to the \textit{S. cerevisiae} mitochondrial probes, and it presumably represented nuclear DNA (data not shown). Some-

agreement with the previous observations on these isolates (1, 20).

The most striking observation, when the restriction pattern from various yeast isolates was compared, was that the number of restriction fragments varied substantially (Figs 1 and 2). Thus, the size of mtDNAs among these yeasts is different. The total size of mtDNA was determined by at least five restriction enzymes used in various combinations (data not shown). A group of yeasts belonging to the sensu stricto group showed the size of mtDNA above 64 kb (Table 1). The observed sizes in S. bayanus, S. carlsbergensis, S. monacensis, S. pastorianus, S. paradoxus and S. uvarum are very similar to the sizes previously reported for S. cerevisiae and S. douglasii (34, 37). On the other hand, isolates belonging to the sensu lato group, had smaller mtDNA molecules below 50 kb (Table 1). In the case of S. exigus and S. castellii the sizes found were only 23 kb and 26 kb, respectively. Thus, the proportion of DNA in intergenic sequences in these two species must be drastically lower than that in the sensu stricto group. S. servazzii and S. unisporus have the same size mtDNA, namely 29 kb, which is only slightly larger than that of S. castellii and S. exigus. Even if S. servazzii and S. unisporus are closely related (20), their restriction patterns are substantially different (data not shown). S. dairensis and S. kluveri contain larger mtDNA molecules of 48 and 49 kb, respectively, but their restriction patterns were completely different (Table 1, Figs 1 and 2). In conclusion, a great heterogeneity with regard to size and organization of mtDNA exists within the genus Saccharomyces. The mtDNA molecules were examined further to determine other physical characteristics.

**G+C content, G+C clusters and ori/rep**

The G+C/A+T ratios of mtDNA molecules were determined using CsCl gradients and S. cerevisiae mtDNA and nuclear DNA as standards. The G+C content of yeasts belonging to the sensu stricto group is 18 mol% or less, while sensu lato yeasts have a slightly higher G+C content, ranging from 19 to 24.5 mol% (Table 2). As mentioned above, in a few cases, S. exigus, S. servazzii and S. unisporus, two bands containing mtDNA sometimes appeared in the CsCl gradient. In this case only the G+C content of the upper band was determined and is shown in Table 2.

There is a clear tendency in all members of the genus Saccharomyces for mtDNA to exhibit a very low G+C content (Table 2). Some other yeasts, for example Pachytichospora transvaalensis, have a much higher G+C content (6). Thus, a general mechanism which ensures a very low G+C content in the mtDNA molecule must exist in the genus Saacharomyces.

G and C residues could be dispersed randomly in the genome or clustered as is the case with the S. cerevisiae mtDNA molecule. In S. cerevisiae a majority of these G+C clusters contain motifs which are recognized by G+C-cutting restriction enzymes. The isolated mtDNA molecules were examined for the presence of HaeIII and MspI restriction sites (Figs 1 and 2). In general, the patterns obtained could be divided into two groups: sensu stricto yeasts gave 25 or more restriction fragments, and sensu lato yeasts below 20 (Figs 1 and 2). On the basis of the sizes and G+C contents of the various mtDNAs, it was possible to calculate the number of restriction sites for molecules with a random distribution of G and C residues (Table 2). It should be noted that for mtDNAs of the sensu stricto group it was difficult to determine the precise number of fragments, because some were too small or they overlapped with others on the gels. In the group of sensu stricto yeasts the predicted number of fragments is three or four (Table 2), and this is about one order of magnitude lower than the observed number of sites (Figs 1 and 2). The numbers of ori/rep sequences occurring in these yeasts were also estimated (Table 1). S. cerevisiae has eight ori/rep sequences which exhibit some sequence polymorphism (12). When S. cerevisiae mtDNA was digested with different restriction enzymes, up to eight different restriction fragments in some digests gave a positive signal with

the orilrep probe. The approximate number of the orilrep sequences was estimated in a similar way in other species. The maximum number of fragments giving a positive signal upon examining several digests was then taken as the number of sequences per genome. The number varied from four to eight among different sensu stricto species (Table 1). Isolates which seem to be more closely related on the basis of their nuclear rRNA sequences (20), also showed similar numbers of orilrep sequences. For example, S. bayanus and S. uvarum both contain four orilrep sequences, and S. douglasii and S. paradoxus contain six or seven orilrep sequences, respectively. In addition, S. cerevisiae and S. paradoxus, which are very closely related (20),

Resemble each other in the number of ori/rep sequences more than they resemble S. bayanus (Table 2).

In sensu lato yeasts the genome organization, so far as G+C clusters are concerned, seems to be different from sensu stricto yeasts. While the genome size was smaller than that of the sensu stricto group, a similar number of HaeIII or MspI sites was predicted for sensu lato yeasts, because of a slightly higher G+C content (Table 2). In contrast to the sensu stricto group, the discrepancy between the predicted and observed HaeIII and MspI sites is substantially smaller than in the sensu lato group. The obtained number of restriction fragments is only one to two and a half times higher than the number predicted on the basis of randomness. Thus, the distribution of G and C residues is likely to be more random in yeasts of the sensu lato group than of the sensu stricto group. Furthermore, in contrast to yeasts of the sensu stricto group, the sensu lato yeasts did not yield any signal with the ori/rep probe (Table 1). Therefore, two classes of mtDNA exist among yeasts belonging to the genus Saccharomyces. The sensu stricto group has a larger mtDNA molecule with abundant G+C clusters recognized by HaeIII and MspI, and ori/rep sequences, while mtDNA of the sensu lato group is smaller, lacks ori/rep sequences, and apparently does not contain an extensive number of G+C clusters with HaeIII and MspI sites.

In S. cerevisiae, G+C clusters are involved in genetic instability of mtDNA through the promotion of the physical generation of petite mtDNA molecules and their enhanced transmission (28). Therefore, the two groups of yeasts, with different organizations of their mtDNA, were compared for their ability to generate petite mtDNA molecules.

Genetic stability of mtDNA

When stationary cultures of different yeast isolates were plated onto medium with a limited concentration of glucose (GGlyYP) in all cases except one large and small colonies appeared. These small colonies did not grow on glycerol medium, but could grow on the glucose medium. The smaller colonies, when transferred to plates containing tetrazolium remained colourless, indicative of their inability to respire aerobically. The frequency of the respiration deficient colonies varied from 0 in S. kluyveri to 67% in S. uvarum (Table 3). The mtDNA of several mutants was then examined. In some of the petite mutants mtDNA was not detected at all, either by analysis of total DNA with a molecular probe or by running a CsCl gradient (data not shown). Apparently, these mutants were rho⁻. However, a majority of respiratory-deficient colonies still yielded distinctive mtDNA bands in CsCl gradients, and these bands varied in intensity and position (data not shown). A few mtDNA molecules from the non-respiring strains of various species were subjected to restriction analysis. When restriction patterns were compared with those of the respective wild-type strains of the corresponding species, most of the fragments characteristic for the wild-type mtDNA molecules were missing from the patterns of the mutants (data not shown). Usually, only a very limited number of restriction sites was retained in petite mtDNA. The mutant analysed in Fig. 3 retained only three restriction sites. When this mtDNA was cut with any of these three restriction enzymes, a fragment of about 1 kb was obtained. Thus, only a short segment of wild-type mtDNA was retained in the mutant (Fig. 3). This observation is in accord with the characteristics of S. cerevisiae petite mtDNA where a short segment is multiplied to reach a similar size to that of...
Mitochondria1 genomes of Saccharomyces yeasts is not a simple function of the size and organization of the mtDNA molecules (Tables 1 and 3).

When a mitochondrial mutant is induced in S. cerevisiae, it takes about 8 h growth in a rich medium to obtain the first homoplasmic clones (14). This segregation process can be studied as induction of petites with ethidium bromide (Et-Br) (16, 33). When S. cerevisiae was treated with Et-Br, practically all colonies turned into petites after 8 h growth at a very low concentration of Et-Br (Table 3). Such a high inducibility was also found among all yeasts belonging to the sensu stricto group (Table 3). At higher concentrations of Et-Br almost all colonies turned into petites, and at concentrations above 50 mg l⁻¹ the cells did not survive the treatment.

Inducibility of petites in the sensu lato yeasts exhibited a different pattern from that of sensu stricto yeasts (Table 3). After attempted induction with sublethal concentrations of Et-Br (50 mg l⁻¹ and below), a majority of cells were found to be respiration-competent. The frequency of petites was only moderately elevated, i.e. for S. castellii the highest frequency obtained upon induction was about fourfold higher than the spontaneous frequency (Table 3). By comparison, in sensu stricto yeasts the frequency of petites at equal concentrations of Et-Br reached 100%. Concentrations above 50 mg l⁻¹ were lethal for sensu lato yeasts as they were for S. cerevisiae. When the exposure to Et-Br was prolonged from 8 to 20 h at concentrations of 25–50 mg Et-Br l⁻¹, the frequency of petites increased and passed 50% in all sensu lato yeasts, except for S. kluyveri (data not shown).

In the case of S. kluyveri no petites could be induced. Even after prolonged growth at 50 mg Et-Br l⁻¹, all surviving colonies were respiration-competent. On the basis of the above experiments (Table 3) the yeasts belonging to the genus Saccharomyces could be divided into three groups: (i) highly inducible yeasts of the sensu stricto group, (ii) moderately inducible yeasts of the sensu lato group, and (iii) S. kluyveri which is a petite-negative yeast.

Fig. 3. mtDNA from S. dairensis respiration-competent wild-type strain (a) and a spontaneously generated petite strain, Y143 (b) was isolated and digested with various restriction enzymes: Accl (lane 1), BamHI (2), BglII (3), CfoI (4), ClaI (5), DraI (6), EcoRI (7), HindIII (8), NsiI (9), PstI (10), PvuII (11), SalI (12), Sphi (13), XbaI (14) and XhoI (15). Fragments were separated on a 1% agarose gel. Note that petite mtDNA contains restriction sites of only three enzymes, 1, 2 and 6, which all generate a single fragment of about 1 kb. Lambda DNA digested with BstEII was used as a size marker, M.

the wild-type mtDNA molecule (2, 33). Petite mtDNA molecules, characterized by extensive deletions, were found in all tested species from the sensu stricto as well as sensu lato groups, but not in S. kluyveri. It is of interest to note that the observed frequency of petites is not a simple function of the size and organization of the mtDNA molecules (Tables 1 and 3).

Origin of the modern mtDNA molecules

The genus Saccharomyces at present contains ten recognized species (1, 20), but only in one of them, S. cerevisiae, has the nuclear genome been thoroughly characterized (for a review, see 15). Karyotypes of some other species have been partially characterized (24, 35), and partial sequences of nuclear rRNA genes have been determined (18, 20). The data on mtDNA molecules have previously been limited to some isolates of S. cerevisiae (for a review, see 37), and single isolates of S. douglasii (34), S. exigua (7) and S. kluyveri (23). In the literature it is also possible to find some characterization of the yeast strain, NCYC74, which was incorrectly designated as S. carlsbergensis (29, 32). However, this strain was later suggested and shown to be an isolate of S. cerevisiae (19). Thus, mtDNA of S.
J. Piiskur and others

carlsbergensis has not been characterized previously. Based on various molecular comparisons, it appears that so far the sensu stricto complex has four species: S. cerevisiae, S. paradoxus (synonym S. douglasii), S. bayanus (synonym S. uvarum) and a hybrid, S. pastorianus (synonym S. carlsbergensis). The other six species belong to the sensu lato group (1). However, there is still much uncertainty regarding the phylogenetic relationship among these as well as other isolates belonging to the genus Saccharomyces.

When mtDNA isolated from various Saccharomyces yeasts was digested with various restriction enzymes unique restriction patterns were observed for each isolate (Figs 1 and 2). It is interesting to stress that in S. cerevisiae HaeIII and MspI cut predominantly in the intergenic sequences which are more variable among various strains than the coding regions (37). When several isolates of S. cerevisiae were compared for their HaeIII and MspI restriction patterns, only about 50% of the bands were identical (25, 32). Thus, polymorphism can be expected among different isolates belonging to the same species. When different species were analysed, HaeIII and MspI generated specific fingerprint patterns which could be used for identification and classification of the same, as well as related isolates/species (Figs 1 and 2). Among isolates belonging to the sensu stricto group of yeasts similar restriction patterns were observed in a few cases and in general they confirmed previous molecular comparisons (20, 24). A similar restriction pattern was observed in S. carlsbergensis, S. monacensis and S. pastorianus (Figs 1 and 2), which implies that these mtDNA molecules have a common origin. S. carlsbergensis and S. pastorianus have previously been described as hybrid yeasts which were generated by an interspecific fusion/cross between two different yeasts (19, 20). One of the parental strains in this ‘fusion/cross’ was S. cerevisiae, and S. monacensis was suggested as the second one (17, 24). It is interesting to point out that both sets of parental chromosomes are present in the case of nuclear DNA (19), while only the non-S. cerevisiae mtDNA can be found in S. carlsbergensis/S. pastorianus (Figs 1 and 2). This mtDNA contains a similar number of ori/rep sequences to S. bayanus, S. monacensis and S. uvarum (Table 2). Presumably, S. pastorianus/carlsbergensis inherited mtDNA only from the non-S. cerevisiae parent. However, only further characterization of these isolates will provide more insight into the origin of the above hybrids.

The sensu lato yeasts contain smaller mtDNA molecules which do not contain an excess of HaeIII and MspI restriction sites (Table 1). This group shows more variability regarding the size of mtDNA than the sensu stricto group. Also the restriction patterns of the sensu lato group differ widely (Figs 1 and 2). The size of the mtDNA varies from 23 kb in S. exigus, which apparently does not contain extensive intergenic sequences, to 48 kb in S. dairiensis and 49 kb in S. kluyveri (Table 1). The latter two yeasts are not closely related (18, 20). Two more closely related species, S. servazzii and S. unisporus (18, 20), have similarly sized mtDNA (29 kb). On the other hand, another pair of closely related species, S. castelli and S. dairenensis (18, 20), show a twofold difference in size. In general, it seems that the size of mtDNA is very variable within the genus and could have changed frequently during evolution of each modern sensu lato species. The mechanism determining the size of mtDNA is not known at present. The difference between the predicted and observed number of HaeIII and MspI sites in sensu lato species is not substantial (about two and a half times), which is very different from the situation in the sensu stricto group (Tables 1 and 2). The sensu lato group also did not give any signal with the ori/rep probe, suggesting that this sequence is not present in these yeasts. Therefore, it is expected that intergenic sequences in sensu lato species consist predominantly of A+T-rich stretches. Apparently, the type and abundance of G+C-clusters which carry HaeIII and/or MspI sites, and especially ori/rep, evolved in the mtDNA molecule after separation of the sensu stricto and sensu lato yeasts. At this point it is interesting to mention that different mitochondrial G+C clusters evolved several times among Ascomycetes. For example, Kluveromycetes lactis, a fairly close relative of the genus Saccharomyces, contains a different type of G+C cluster which is recognized by SacII (30). While in general it is still unclear what kind of role different G+C clusters play in the genome, it seems that in S. cerevisiae some of the G+C clusters, especially ori/rep, are actively involved in transmission of mtDNA to progeny (4, 25, 40). In this way certain G+C clusters may be actively preserved in mitochondrial genomes.

However, although fewer G+C clusters are present in the sensu lato group, this does not stabilize their mtDNA against spontaneous generation of petite mtDNA molecules (Fig. 3). Spontaneous respiration-deficient mutants were found at high frequency in all isolates, except S. kluyveri (Table 3, Fig. 3). This yeast behaves as a petite-negative even upon strong induction with Et-Br. This characteristic, which distinguishes S. kluyveri from the rest of the Saccharomyces yeasts, is supported by other observations (20, 35) which also suggest that this yeast should belong to a separate genus. Some other genera, i.e. Kluyveromyces, Zygosaccharomyces and Torulaspora, which are close relatives of Saccharomyces, also seem to be petite-negative (data not shown). Thus, it seems that the petite-positive character evolved specifically in the progenitor of the sensu lato and sensu stricto yeasts after separation from S. kluyveri and other related genera.

In conclusion, the following evolutionary development of the mitochondrial genome in the Saccharomyces yeasts is proposed. The mtDNA molecule in the progenitor of the Saccharomyces yeasts was relatively small and genetically stable, and this yeast was petite-negative. The petite-positive character evolved after the sensu lato and sensu stricto yeasts had separated
from *S. kluveri*. Later, the origin of the *sensu stricto* group and its separation from the *sensu lato* group coincided with the appearance of various mitochondrial G+C-rich clusters, including ori/rep. These biologically active sequences have contributed markedly to the further evolution of the size and genetic instability of the *sensu stricto* mitochondrial genome.

ACKNOWLEDGEMENTS

This work was supported by the Danish Research Council and the Carlsberg Foundation. The authors thank A. Kahn and T. Nilsson-Tillgren for their stimulating comments on this work. C. Kurtzman is acknowledged for providing some of the yeast strains employed in this study.
