Eighteen isolates of a nonchromogenic, slowly growing, non-tuberculous species of the genus Mycobacterium were cultured from respiratory specimens obtained over the last eight years from 17 patients in the Netherlands. These isolates were grouped because they revealed a unique 16S rRNA gene sequence and were related to Mycobacterium xenopi. None of the 17 patients met the American Thoracic Society diagnostic criteria for non-tuberculous mycobacterial disease, which distinguishes the novel isolates from the related species, M. xenopi. A polyphasic taxonomic approach, including identification by biochemical and phenotypical analysis, hsp65 gene sequencing and PCR restriction enzyme pattern analysis, and sequence analyses of the rpoB gene and 16S–23S internal transcribed spacer supported the separate species status of the novel isolates. The name Mycobacterium noviomagense sp. nov. is proposed for the novel strains. The type strain is NLA000500338T (=DSM 45145T =CIP 109766T). A more distinctive taxonomy of NTM is a prerequisite for the assessment of their clinical relevance.

Improved detection and identification techniques have triggered renewed interest in non-tuberculous mycobacteria (NTM) and their role as opportunistic pathogens. PCR techniques and 16S rRNA gene sequence analysis have brought to light a series of novel NTM species, however, the clinical relevance of these species is not always clear (Tortoli, 2003; Tortoli et al., 2001; Griffith et al., 2007).

NTM infections present predominantly as chronic pulmonary disease, although extrapulmonary and disseminated infections have also been described (Griffith et al., 2007). Local immunosuppression due to pre-existing pulmonary disease and systemic immunosuppression, e.g. in haematological malignancy, immunosuppressive medication and HIV/AIDS, have been identified as predisposing factors (Griffith et al., 2007) for NTM infections. Infection has to be differentiated from contamination and pseudo-infection, characterized by the recovery of single NTM isolates from the respiratory or digestive tract without signs of disease (Griffith et al., 2007; Portaels, 1995). Their ubiquitous presence in the environment, survival in flowing water systems and resistance to disinfectants implies that NTM often represent laboratory or medical equipment contamination (Griffith et al., 2007; Portaels, 1995; van Klingeren & Pullen, 1993). The diagnostic criteria proposed in a Statement by the American Thoracic Society (ATS) are designed to differentiate between true infection and pseudo-infection or contamination, based on clinical, radiological and microbiological features (Griffith et al., 2007).

This study describes the grouping of 18 previously unknown Mycobacterium isolates with identical 16S rRNA gene sequences and with a high degree of gene sequence similarity to strains of Mycobacterium xenopi. As other features of these novel strains were highly distinct...
from *M. xenopi* and the clinical relevance differed significantly between the new isolates and *M. xenopi*, the 18 isolates are proposed to represent a novel species of the genus *Mycobacterium*.

The 18 novel isolates were acquired from pulmonary samples (13 from sputum, 4 from broncho-alveolar lavage fluid and 1 from a post-mortem lung biopsy) of 17 patients in the Netherlands between January 1999 and January 2007. To determine clinical relevance, we examined the medical records of all 17 patients; their baseline characteristics are displayed in Table 1. The predominance of male patients, mean age and history of chronic pulmonary disease are comparable with previous NTM studies (Griffith *et al.*, 2007; Henry *et al.*, 2004). None of the patients had clinical and radiographic features suggestive of mycobacterial lung disease; one was systemically immunocompromised due to HIV co-infection. The post-mortem lung biopsy sample showed histological features of bronchopneumonia and invading bacteria, without features of mycobacterial disease such as granuloma formation. All patient samples were negative for acid-fast bacilli on direct microscopy which suggested the presence of a low number of NTM in the original sample or contamination after sample division for culture and microscopy. Although follow-up sputum cultures were performed for 16 patients, only one patient produced another culture that was positive for the novel strains. All others had a single positive culture. Based on these findings, none of the patients from whom the novel strains were isolated met the ATS criteria for pulmonary NTM disease (Griffith *et al.*, 2007). Good clinical response to non-antimycobacterial regimes, the subsequent establishment of alternative diagnoses and the observed spontaneous conversion to negative cultures suggested that the novel strains were not the causative agent of these patients’ symptoms. The novel strains therefore seem to have no clinical relevance, which distinguishes them from phylogenetically related, but more pathogenic species such as *M. xenopi* and *Mycobacterium heckeshornense* (Griffith *et al.*, 2007; Roth *et al.*, 2000; van Ingen *et al.*, 2008).

Two patients received antituberculosis treatment for an average period of 10 weeks, after a presumptive diagnosis of TB. Treatment of patients not meeting the ATS diagnostic criteria is potentially harmful to patients in terms of adverse effects and costs (van Crevel *et al.*, 2001).

Geographical clustering of the patients was observed, favouring the south-east of the Netherlands, in adjacent areas of the Limburg (7 cases), Gelderland (5 cases) and Noord-Brabant (2 cases) provinces. This clustering suggested the presence of the novel strains in specific local environments or tap water. Since the clustering was seen geographically, but not over time, contamination from medical machinery or the laboratories involved seemed less likely.

All of the novel isolates were subjected to laboratory diagnosis by the National Mycobacteria Reference Laboratory of the National Institute for Public Health and the Environment (RIVM). The RIVM provides molecular identification, drug susceptibility testing and epidemiological typing of mycobacterial isolates for all healthcare institutions in the Netherlands.

Biochemical identification and HPLC analysis of cell-wall mycolic acid content were performed using previously described approaches (Lévy-Frêbault & Portaels, 1992; Centers for Disease Control and Prevention, 1996). Eight isolates (4 *M. xenopi*, 4 of the novel strains) were subjected to biochemical testing. The results are detailed in Table 2. Morphologically, two patterns were clearly discernible. On Middlebrook 7H10 media, the *M. xenopi* isolates were scotochromogenic, showing yellow pigmentation, whereas

colonies of the novel species were smaller and nonchromo-

genic. All M. xenopi isolates grew at 45 °C, as previously

reported (Torkko et al., 2000), but the novel strains were

unable to grow at this temperature (Table 2). Biochemically,

the novel isolates were indistinguishable from the cluster

comprising M. xenopi, Mycobacterium botnienense and M.

heckeshornense, with negative results for urease, Tween 80

hydrolysis, niacin production, nitrate reductase, acid

phosphatase and semi-quantitative catalase. HPLC of the

novel isolates revealed a pattern characterized by one early

and one late cluster of peaks, a profile similar to that of M.

xenopi, M. heckeshornense and M. botnienense (Fig. 1).

The HPLC mycobacterium library (available online at http://

www.MycobacToscana.it) was used for this comparison.

Susceptibility testing was performed for eleven of the novel

isolates from eleven patients using the agar dilution

method (van Klinger et al., 2007). For the novel isolates,

we recorded in vitro resistance to rifampicin (MIC 2

mg l⁻¹), resistance or intermediate susceptibility to

ethambutol (MIC 10–20 mg l⁻¹) and intermediate sus-

ceptibility to isoniazid (MIC 0.5–1 mg l⁻¹). The novel

species proved susceptible in vitro to streptomycin,

cycloserine, prothionamide, amikacin, ciprofloxacin, clo-

fazimine, clarithromycin and rifabutin. The drug suscept-

ibility pattern for the novel isolates differed slightly from

clinical isolates of M. xenopi tested at RIVM which were

mostly susceptible, in vitro, to rifampicin (MIC 0.5–

1 mg l⁻¹). These results for M. xenopi are in accordance

with previous reports (Dauendorf et al., 2002).

For molecular identification, sequencing of the full 16S rRNA

gene and 16S–23S internal transcribed spacer (ITS), partial

rpoB and hsp65 genes, and PCR restriction enzyme pattern

analysis (PRA) of the hsp65 gene were performed using

previously described methods (Kim et al., 1999; Roth et al.,

1998; Springer et al., 1996; Telenti et al., 1993). The sequences

obtained were compared with the GenBank/EMBL (NCBI,

The full 16S rRNA gene sequence for the novel species showed

96 % sequence similarity with that of M. xenopi and was 97 %

similar to those of M. heckeshornense and Mycobacterium

shimoides. A sequence difference of 1 % has been proposed in

the literature as the threshold for the designation of a novel

species (Hall et al., 2003; Tortoli, 2003).

The full 16S rRNA gene sequence of the novel strains was

aligned with those of reference strains of the closest related

cytocobacteria using CLUSTAL_X software (Thompson et al.,

1997). The resulting topology and tree, inferred by

neighbour-joining and visualized using the LOFT software

package (van der Heijden et al., 2007) were evaluated by

bootstrap analyses based on 1000 resamplings (Fig. 2).

Analysing only the hypervariable region A of the 16S rRNA

gene (151 bp), we found a 100 % match in the GenBank/

EMBL database to a strain designated 'most closely

resembling M. xenopi', as reported by Hall et al. (2003).

Analysis of the phenotypic and genetic characteristics of the

novel species (Table 2, Figs 1, 2 and 3) demonstrates that

very subtle 16S rRNA gene sequence differences can be

associated with extensive divergence from the closest

related species. This brings into question the use of

monophonic identification methods.

Analysis of the 16S–23S ITS region revealed mixed

sequence patterns for all 18 novel isolates, even from

single colony cultures, and necessitated cloning. For

cloning of the ITS, amplicons were generated using primers

provided with the INNO LiPA Mycobacteria v2 kit

(Innogenetics), and cloned in the PGEM-T Easy vector

(Prome ga) according to the manufacturer’s instructions.

Thirty colonies of transformed Escherichia coli strain DH5F

were picked for each sample, cultured and used to prepare

plasmid DNA using the QIAprep 96 Turbo BioRobot kit

(Qiagen). For sequencing of the ITS region cloned into the

PGEM-T vector, the universal vector primers M13 (−21) and

M13rev were used on the plasmid preparation as

target. Cloning resulted in the recognition of two distinct

copies of the ITS, both with <68 % sequence similarity to

M. xenopi. A 93 % sequence similarity was noted between

the two ITS copies. The presence of multiple copies of the

16S–23S ITS region, thus possibly multiple rRNA operons,

Fig. 1. Mycolic acid patterns of Mycobacteri-

a. noviomagenese sp. nov. obtained by

HPLC analysis. One early and one late cluster

of peaks are present, similar to M. xenopi. The

first (left) and last (right) peaks are the low and

high weight molecular standards.

http://www.microbiologyresearch.org
is unexpected. This phenomenon has not been described for *M. xenopi* or for closely related slow-growing NTM species and thus supports the separate species status of the novel isolates.

The *rpoB* gene sequence of the novel isolates was 95% similar to that of the recently described species *Mycobacterium seoulense* and only 92% similar to that of *M. xenopi*. For the *hsp65* gene sequence, the most closely related sequences (95%) were found among members of the *Mycobacterium avium* complex and *Mycobacterium brandeni*, with <93% similarity to *M. xenopi*. The considerable divergence in these two targets from the otherwise related cluster comprising *M. xenopi*, *M. botniense* and *M. heckeshornense* supports the separate species status of the novel isolates. The *hsp65* and *rpoB* gene sequences were aligned with those of related mycobacterial species, as for the 16S rRNA gene sequence. The resulting topologies and trees are available as Supplementary Figs S1 and S2 (in IJSEM Online).

The *hsp65* gene PRA results for the novel isolates, *M. xenopi*, *Mycobacterium tuberculosis* H37RvT and *M. botniense* ATCC 700701T are shown in Fig. 3. For the novel isolates, digestion with *Bst*EII resulted in fragments of 240/120/100 bp, digestion with *Hae*III gave fragments of 130/10/70/45 bp. A PRAsite (http://app.chuv.ch/prasite/index.html) comparison showed this to be a unique fragment length combination. Isolates of *M. xenopi* and *M. tuberculosis* tested simultaneously were correctly identified using the PRAsite database; no entry was found for *M. botniense*.

**Description of Mycobacterium noviomagense sp. nov.**

*Mycobacterium noviomagense* (no.vi.o.ma.gen’se. N.L. neut. adj. pertaining to Noviomagus, the Roman name of...
the major city in the endemic region in the Netherlands and the location of the reference hospital; current name: Nijmegen).

Acid-fast and Gram-positive rods. Colonies are nonchro-
mogenic and appear after 4 weeks of culture at 37 °C, no
growth occurs at 45 °C. Negative in tests for urease, Tween
80 hydrolysis, nacian production, nitrate reductase, acid
phosphatase and semi-quantitative catalase. Can be readily
identified by its unique rRNA gene sequences.

The type strain, NLA000500338T (=DSM 45145T=CIP 109766T), was recovered from sputum.
