SUMMARY
The RNA content of four different CMV strains was investigated. All RNA preparations always contained the four major RNA species described by Kaper & West (1972), while most preparations also contained several minor RNA species. The four largest RNAs were separated by sucrose density-gradient centrifuging and by electrophoresis on polyacrylamide gels. Combination experiments suggest, for all strains, that the genome consists of the three largest RNAs (1 + 2 + 3), while RNA 4 is not required for infectivity.

The distribution of RNAs in the capsids could not be established unequivocally, and the situation possibly differs in different strains.

INTRODUCTION
Cucumber mosaic virus (CMV) preparations contain a single sedimenting nucleoprotein component with a mol. wt. of 5 to 5.5 x 10^6 containing about 1 x 10^6 daltons of RNA (Kaper, Diener & Scott, 1965; Dupont et al. 1968; van Regenmortel, Hendry & Baltz, 1972). However, the RNA from CMV has several sedimenting components with estimated mol. wt. of 1.90, 0.77 and 0.33 x 10^6 (Kaper et al. 1965). Infectivity was associated with the fastest-sedimenting component and the two smaller components were thought to be degradation products. Electrophoresis of CMV-RNA in polyacrylamide gels resolves six species, the fastest-migrating two being in small amount (Kaper & West, 1972).

CMV therefore appears to be similar to the members of the bromovirus group, broad-bean mottle, brome mosaic and cowpea chlorotic mottle viruses, each of which has a single

* Present address: Station de Pathologie, CRAAG, Domaine Duclos, Petit-Boug, Guadeloupe, French West Indies.
sedimenting nucleoprotein component yet several RNA components (Kodama & Bancroft, 1964; Bockstahler & Kaesberg, 1965; Bancroft et al. 1968). Electrophoresis of RNAs of bromoviruses on polyacrylamide gels resolves four species for each virus; the heaviest two or three species are needed for infection (Bancroft, 1971; Lane & Kaesberg, 1971; Bancroft & Flack, 1972; Hull, 1972). Preparations of each of these viruses consist of a mixed population of nucleoprotein particles containing either of the two heavier RNA species alone; brome mosaic and cowpea chlorotic mottle virus preparations also have particles which contain one piece of each of the two lighter RNA species, whereas broad-bean mottle virus has particles which contain several, probably four, pieces of the lightest RNA. This gives density heterogeneity (Lane & Kaesberg, 1971; Bancroft & Flack, 1972; Hull, 1972). Lot & Kaper (1973) showed that CMV is also heterogeneous in CsCl density-gradient equilibrium experiments although to a much lesser degree than brome mosaic virus. For this reason, and because the nucleocapsid had to be stabilized by formaldehyde, which destroys the infectivity, the differences in buoyant density could not be used for separation purposes.

CMV has some properties in common with alfalfa mosaic virus (Hull, 1969; Bol, van Vloten-Doting & Jaspars, 1971). Alfalfa mosaic virus has four nucleic acid species which correspond to four nucleoprotein components (Bol et al. 1971). The total genome of alfalfa mosaic virus is contained in the three largest RNA species but these are not infectious unless either coat protein or the smallest RNA species is present (van Vloten-Doting, Dinjanz-Versteegh & Jaspars, 1970; Bol et al. 1971).

In this paper we present data obtained in four different laboratories on the RNAs found in several strains of CMV and show that the three largest RNA species are needed for infection. Neither the coat protein nor the smaller RNA species play a role in the infectivity of this virus.

**METHODS**

**Strains and purification.** Strain CMV-S, isolated from squash and originally obtained from Dr M. H. V. van Regenmortel was grown in squash (Cucurbita pepo. L. var. Caserta Bush) for 7 to 8 days and purified by the method of van Regenmortel (1964) ("CMV-S1") or cultured in tobacco (Nicotiana tabacum L. var. Samsun NN) and purified like alfalfa mosaic virus as described by van Vloten-Doting & Jaspars (1972) ("CMV-S2"). In the latter case, after the second high-speed centrifuging, the virus was further purified by centrifuging in an MSE BXIV zonal rotor using isokinetic gradients of 14 to 30% sucrose in 10⁻² M-NaH₂PO₄, 10⁻³ M-EDTA, adjusted to pH 7.0. The virus was then concentrated by ultracentrifuging. The pellets were redissolved in 10⁻² M-NaH₂PO₄, 10⁻³ M-EDTA and 10⁻³ M-NaNO₃, pH 7.0. Strain CMV-D, isolated from tomato was propagated in tobacco (Nicotiana tabacum L. var. Xanthi-nc) for 6 days and purified by the method described by Lot et al. (1972). CMV-Q, isolated from pepper and received from Dr R. I. B. Francki, was cultured in squash and purified as CMV-S. CMV-TAV-898, (one of the two TAV isolates described by Hollings, Stone & Brunt, 1968) was received from Dr M. Hollings and was grown in Nicotiana glutinosa × Nicotiana clevelandii (Christie, 1969) for 10 days. It was purified essentially as described by van Vloten-Doting & Jaspars (1972) but using high-speed centrifuging instead of polyethylene glycol (PEG) concentration.

**Preparation of virus RNA.** RNA from CMV-S and CMV-Q preparations was extracted from a 3.5 mg/ml solution of purified virus using phenol, 0.1 M-NaH₂PO₄ buffer, pH 7.0, 0.15% SDS and 0.02 mg/ml bentonite followed by a tenfold dilution of the aqueous phase and two cycles of ethanol precipitation and resuspension in distilled H₂O. CMV-D RNA
Three functional RNA species in CMV

was also purified by the SDS-phenol method of Lot (1972). CMV-TAV RNA was isolated by direct dissociation of the virus with SDS using the method described for broad bean mottle virus (Hull, 1972). RNA was extracted from CMV-S₂ (10 mg/ml) either as described earlier for alfalfa mosaic virus (van Vloten-Doting & Jaspars, 1967) but, prior to phenol extraction of a virus solution, SDS was added to a concentration of 0.6% instead of pyrophosphate or by direct dissociation of the virus using SDS.

Preparation of protein. CMV-S₂ coat protein was prepared like alfalfa mosaic virus-protein by dissociating the virus with MgCl₂ (Kruseman et al. 1971).

U.v. absorption. For CMV and CMV-RNA the extinction coefficients (E₂₆₀/°) used were 5 and 25 respectively and for CMV protein an extinction coefficient (E₂₆₀/°) of 0.7 was used.

Rate zonal and isopycnic centrifuging in sucrose density gradient. For studying the distribution of RNA species in nucleoproteins, CMV preparations were centrifuged on a linear sucrose gradient in a MSE BXIV zonal rotor as described above.

Isopycnic gradients were formed by layering 1.3 ml each of 60, 65 and 70% sucrose dissolved in buffered D₂O in Spinco SW 39 tubes and stood for 24 h at room temperature. CMV-TAV (1.5 mg) was loaded on to each gradient which was centrifuged for 72 h at 35000 rev/min and 25 °C in a Spinco SW 39 rotor. Banding density was determined refractometrically (Hull & Lane, 1973). For velocity gradient centrifuging of RNA preparations, linear gradients of 6 to 28% or 10 to 30% were centrifuged in a Spinco SW 25 rotor or MSE BXIV zonal rotor, respectively, using conditions described in the legends to the figures.

Infectivity assays. Local lesion assays were made on primary leaves of Vigna sinensis var. Black Eye. In most experiments, plants 7 to 12 days old were shaded 12 to 24 h before inoculation. Leaves were lightly dusted with carborundum prior to inoculation with either a cotton-tipped applicator or a glass spatula.

In some experiments, opposite half-leaves were inoculated with the sample to be assayed and unfractionated CMV RNA of known infectivity level at an arbitrary concentration (the standard). The lesion number of the sample was expressed as a percentage of the standard and recorded as an ‘infectivity index’. In most experiments, assays were done as complete or incomplete blocks (Kleeckoski, 1950). When complete leaves were used, leaves from ten plants were inoculated with a sample and the opposite leaves were inoculated with a standard inoculum.

Gel electrophoresis of RNA. Electrophoresis was done in 2.4%, 2.6% or 3% gels using the buffer system of Loening (1967) or of Peacock & Dingman (1968). Some assays, especially with strain D, were done on 2.5% polyacrylamide, 0.5% agarose gel according to the technique of Peacock & Dingman (1968). Except when specified, gels and buffer systems contained 0.1% SDS. In some experiments gels and samples contained 1 M- or 6 M-urea. Approximately 50 μg RNA, unheated, or heated 10 min at 50 °C, containing 1% SDS was applied on each gel and electrophoresis was carried out for 2 to 4 h at 3 to 5 mA per tube at 4 °C or at room temperature. In specified experiments, samples of RNA were prepared by mixing virus nucleoprotein (1 to 2 mg/ml) with a solution containing phosphate buffer and 1 to 1.5% SDS. Under these conditions, CMV dissociates completely into RNA and protein (Boatman & Kaper, 1973). Gels were either immediately scanned or soaked overnight in 7.5% acetic acid and scanned at 260 nm on a Gilford 2400 spectrophotometer equipped with a linear transport.

For extraction purposes (CMV-S₁ and CMV-D), electrophoresis was done in most experiments in 2.5% polyacrylamide, 0.5% agarose gel without SDS, or in 2.6% to 3% polyacrylamide gels without SDS, for 3 to 4 h at 4 °C and 4 mA per tube. Gels were stained
with 0.3% toluidine blue. After destaining in acetate buffer (10⁻² M-sodium acetate, 10⁻³ M-magnesium acetate pH 5.5), partially stained bands were excised and pooled according to species. The RNA was extracted from the gels by phenol in 10⁻³ M-tris, 10⁻³ M-Na₂ EDTA, 10⁻¹ M-NaCl, pH 7.4. After washing with ether, RNA was precipitated twice with ethanol. The electrophoresis and extraction of species of CMV-TAV RNA was as described for BBMV (Hull, 1972).

For electroelution of CMV-S₂ RNA’s, an apparatus with the specifications described by Popescu, Lazarus & Goldblum (1971) was used. Electrophoresis of RNA liberated by disrupting the virus was performed in 2.4% polyacrylamide gels and Loening buffer diluted 1 in 10 with distilled water. Samples of 0.1 ml of 2 mg/ml virus were loaded on the gel in 1% SDS, 15% sucrose followed by an overlay of 2 ml 0.01% SDS, 5% sucrose.

RESULTS

Nomenclature of CMV RNAs

In previous publications by Diener, Scott & Kaper (1964), Kaper et al. (1965), Kaper & Geelen (1971), Kaper & West (1972) and Kaper & Waterworth (1973), the CMV RNAs were called A, B, C and C₂. In this publication we will use numbers for the RNAs as has been previously done for brome mosaic, broad-bean mottle and cowpea chlorotic mottle viruses. To avoid any confusion we list below the old name and the new number for each CMV RNA species together with the mol. wt. (× 10⁻⁶) (according to Kaper & West, 1972; Kaper & Waterworth, 1973). RNA C₂ = RNA-L mol. wt. 1.07; RNA C₁ = RNA-2, mol. wt. 0.95; RNA B = RNA-3, mol. wt. 0.69; RNA A = RNA-4, mol. wt. 0.33; RNA O = RNA-5, mol. wt. 0.11; RNA OO = RNA-6, mol. wt. 0.01.

Infectivity of fractions and mixtures of fractions from sucrose density-gradient centrifuging of CMV RNA

Three peaks were found when either CMV-S₁ RNA or CMV-D RNA was centrifuged down a sucrose density gradient. For each strain, material from the fastest sedimenting band had the highest specific infectivity, that from the middle band had intermediate specific infectivity and that from the slowest band was not infectious (Diener et al. 1964; Lot, 1972).

In a more systematic approach using CMV-S₁, it was found that mixtures of some RNA fractions were more infectious than the fractions alone (Fig. 1, Table 1). In Table 1 it can be seen that the infectivity of fraction 19 (Fig. 1) is lower than that of the unfraccionated RNA and is increased when a mixture of the smaller CMV RNAs is added but is not increased by the addition of an equivalent amount of TYMV RNA.

A better separation of CMV RNA components was achieved by using a zonal rotor (Fig. 2). Analysis by polyacrylamide gel electrophoresis of fractions from zonal rotor centrifuging showed that RNAs 3 and 4 were well separated but that RNAs 1 and 2 still formed one peak (Fig. 3A to D). The infectivity of the individual fractions was very low but the addition of RNA-3 to the mixture of RNA-1 + 2 increased the infectivity considerably. RNA-3 could not be substituted by RNA-4 and the addition of RNA-4 to the mixture of the other three RNAs had no effect (Table 2). No infectivity was associated with RNA-4 in any of the experiments in which it was tested.

Thus RNA-3 and either or both RNA-1 and RNA-2 are required for infectivity.

Fig. 1. Infectivity of fractions and combinations of fractions after sucrose density gradient centrifuging. Extinction profile of 1.0 mg of CMV-S1 RNA after centrifuging on a linear gradient of 16 to 28 % sucrose in 0.02 M-KH₂PO₄, pH 7.0. Fractions of 1.0 ml were collected. Specific infectivity, expressed as % of infectivity of unfraccionated RNA at the same concentration (2 μg/ml), is indicated by the shaded area.

Fig. 2. Extinction profile of a sucrose density gradient loaded with about 3 mg CMV-S RNA. Before centrifuging the RNA was precipitated with ethanol. The pellet was redissolved in 1 ml dimethyl sulphoxide. After 30 min at 25 °C, 9 vol. of cold buffer were added, and the solution was applied to a BXIV MSE zonal rotor. Centrifuging was for 17 h at 41000 rev/min and 4 °C. Gradient was from 10 % to 30 % sucrose in 10⁻³ M-NaH₂PO₄, 10⁻³ M-EDTA, 10⁻¹ M-NaCl, pH 7.0.

Analytical gel electrophoresis of RNAs from different CMV strains

Electrophoresis of CMV strains D, Q and TAV always revealed the six RNAs described for CMV-S by Kaper & West (1972) (Fig. 4A to E). Only in the case of CMV-S2 were RNA 5 and 6 missing (L. van Vloten-Doting, unpublished results, and Fig. 4B); this may be due to differences in the growing and isolation of the virus. The mol. wt. of the RNAs from CMV-D and Q are not significantly different from those of CMV-S (Kaper & Waterworth, 1973; Marchoux, Douine & Lot, 1973; J. M. Kaper, unpublished results). The RNAs of CMV-TAV, however, are significantly larger: 1 = 1.23 × 10^6; 2 = 1.17 × 10^6; 3 = 0.97 × 10^6; 4 = 0.50 × 10^6 and 5 = 0.17 × 10^6. CMV-TAV RNAs, modified with formaldehyde using the technique of Hull & Lane (1973) appeared even larger, being 1.36, 1.27, 1.04 and 0.49 × 10^6 for 1 to 4 respectively, using formaldehyde modified Escherichia coli ribosomal RNAs as standards. Supporting evidence for these mol. wt. estimates came from co-electrophoresis of CMV-TAV RNA with those of brome mosaic and alfalfa mosaic viruses and using the published mol. wt. estimates of the RNAs of these two viruses (Bol, 1969; Hull, Rees & Short, 1969; Lane & Kaesberg, 1971). However the differences between mol. wt. estimates of CMV-TAV RNA species and those of other CMV strains may reflect the fact that these estimates were made in different laboratories with different techniques.

The relative proportions of RNA species from CMV-S1, D and Q, were estimated by measurements of peak areas from gel traces. RNA-1+2 are 28 to 33% of total RNA; RNA-3 40 to 45% and RNA-4 21 to 25%. For CMV-S2, the ratio of RNA 3 to 4 from

* RNA (1 + 2) bands were excised from gels after a first electrophoresis. RNA was extracted, concentrated and re-run on polyacrylamide-agarose gel. RNA 1 and 2 were then extracted separately. RNA 3 was also re-run after extraction from the first gel electrophoresis.
† Average on ten leaves of cowpea.

SDS-dissociated virus was 2·1:1:0. As the ratio of their mol. wt. is 2·12:1·0 it seems likely that these RNA species are in equimolar proportions. However, the ratios of RNA-3 to 4 from phenol prepared RNA from this strain was variable and significantly smaller. The ratio of RNA-3 to 4 for SDS-dissociated CMV-TAV was larger, being approx. 3·1.

RNA-1 and 2 were never separated well enough to enable reliable estimates of their relative proportions to be made. It is evident from the densitograms (Fig. 4) that the ratio of RNA-1 to 2 varied considerably between strains. However, there was also variation in this ratio between preparations of some of the strains, possibly due to differences in culture and isolation methods.

Infectivity of combinations of RNAs separated by gel electrophoresis

In Table 3 are shown the results of combination experiments performed with RNAs extracted or eluted from polyacrylamide or agarose-polyacrylamide gels. In all cases the mixture of RNA-1 + 2 + 3 had the highest infectivity. The mixtures of RNA-1 + 3 and RNA 1 + 2, however, always showed an intermediate infectivity suggesting possible con-
Three functional RNA species in CMV

Fig. 5. Effect of CMV coat protein on infectivity caused by CMV-S2 RNA 1+2 or CMV-S2 RNA 1+2+3. RNA (12 µg/ml) was combined shortly before inoculation, in a 1:1 vol. ratio with protein solutions of increasing concentration. ×—×, protein added to a mixture of RNA 1 and 2; ○—○, protein added to a mixture of RNA 1, 2 and 3. The ratio of RNA molecules to protein molecules was calculated using a mol. wt. of 24000 for the protein subunit (Hill & Shepherd, 1972; van Regenmortel et al. 1972) and an average mol. wt. of 1 × 10^6 for the three large RNAs (Kaper & West, 1972). Lesion number is the average of seven half-leaves.

Attempts to correlate the RNA components with nucleoprotein components

CMV sediments as a single peak on sucrose density gradients. However, analysis of the RNA content of fractions showed that the slower-sedimenting fractions were enhanced in RNA-2 (Fig. 6C, G) while the faster-sedimenting fractions contained relatively more RNA-1 (Fig. 6E and I); particles containing RNA-3 and 4 were found in all fractions but were more abundant in the fastest sedimenting fractions. Fig. 6A and F supports the conclusion drawn from Table 3 that RNA-1 is indispensable for infectivity.

Because CMV degrades in high salt concentrations (Kaper et al. 1965) it is not possible to use isopycnic CsCl gradients for separation of nucleoproteins.

CMV-TAV formed a single band at ρ = 1.34 g/ml on sucrose/D_2O isopycnic gradients (Fig. 7). Analysis of the RNA content of fractions from such a gradient (Table 5) showed that the denser fractions were richer in RNA-1 and the lighter in RNA-3.

† The amount of each RNA was estimated by measuring each peak area from polyacrylamide gel electrophoresis. The virus in the fractions was concentrated by precipitation with 10% PEG and then was dissociated by SDS.

DISCUSSION

From the results presented it is evident that all the CMV strains examined possess the four major RNA components described by Kaper & West (1972). The highest infectivity is always associated with a mixture of the three largest RNAs. The fact that RNA-1 + 2 is always infectious too, could suggest that RNA-3 is not really required for infectivity. Bancroft (1971) described a similar situation for cowpea chlorotic mottle virus but Bancroft & Flack (1972) concluded that the infectivity of cowpea chlorotic mottle virus RNA-1 + 2 was due to contamination with RNA-3. However, Hull (1972) was unable to show with BBMV that RNA 3 was necessary for infection. In the case of CMV, the results suggest that RNA 1 + 2 + 3 constitute the genome. In contrast to the situation, in alfalfa mosaic virus this genome does not need coat protein for activation. So although CMV has a number of physical and biological properties in common with alfalfa mosaic virus (Hull, 1969; Bol et al. 1970) the requirements for infectivity are similar to brome mosaic and cowpea chlorotic mottle viruses (Lane & Kaesberg, 1971; Bancroft & Flack, 1972).

Another indication of the multicomponent nature of viruses is the effect of dilution on infectivity (see van Vloten-Doting, Kruseman & Jaspars, 1968). In several experiments, however, the dilution curve for CMV was of the ‘single-hit’ type (unpublished results). A similar situation has been reported for brome mosaic virus (Lane & Kaesberg, 1971), broad-bean mottle virus (Kodama & Bancroft, 1964) and for cowpea mosaic virus.
A van Kammen, personal communication) all three being multicomponent viruses, the first two with a tripartite and latter with a bipartite genome. A possible explanation could be that, in these cases, one of the essential components is present in a limiting amount.

The situation concerning the distribution of RNA in the nucleocapsids is not clear. The simplest possibility is that, like brome mosaic and cowpea chlorotic mottle viruses (Lane & Kaesberg, 1971; Bancroft & Flack, 1972) there are three types of nucleoprotein particle, the densest containing RNA-1, an intermediate one containing RNA-3+4 and the lightest containing RNA-2. The analysis of velocity gradient bands (Fig. 6) and of isopycnic banding of CMV-TAV in sucrose/D$_2$O gradients (Fig. 7) indicates that this might be the case with CMV. The equimolar proportions of RNAs-3 and 4 in strain S$_2$ of CMV would seem to add further support to this suggestion. However, RNA-3 and 4 of CMV-TAV are not found in equimolar proportions. Furthermore for CMV-S, Lot & Kaper (1973) suggest that capsids contain, in descending order of buoyant density: RNA-1, RNA-2+5, RNA-3+4. For CMV-S$_2$ this could not be the case as RNA-5 is missing and also the capsids containing RNA-2 sediment slower than those containing RNA 3+4. These differences could be explained by suggesting that there are two kinds of RNA-2; the functional molecule and a degradation product of RNA-1 (together with RNA-5). If this is so, then in CMV-S$_{2}$ the true species 2 dominates and in CMV-S$_{2}$ it is the degradation product which is most common. This hypothesis of in vivo degradation could also explain the fluctuations of infectivity during the course of infection (Marrou, Marchoux & Migliori, 1971; Barbara & Wood, 1972). However, the possibility that RNA-5 is a host RNA, encapsidated by the virus capsid under certain circumstances, cannot be overlooked since pseudovirions have been reported for tobacco mosaic virus (Siegel, 1971).

L.V.V.-D. would like to thank Dr E. M. J. Jaspars for enthusiastic discussions and Lyda Neeleman for assistance with the experimental work; R.H. would like to thank Dawn Aldous for technical assistance, and G.M. and J.M. give thanks to C. Esvan"and Marcelle Clement.
