The protective immune response against porcine circovirus 2 (PCV2) infection in mice was characterized using flow cytometric analysis (FCM), assays of antibody (of different IgG isotypes) and viraemia, and histopathological examination. An open reading frame 2 plasmid (pORF2) and the capsid protein (Cap) of PCV2 were used as DNA and subunit vaccines, respectively.

In FCM analysis, although pORF2 and Cap alone showed comparable efficacy in eliciting lymphoproliferative responses and Cap-specific CD4\(^+\) T cells, pORF2 was superior to the Cap protein in triggering CD8\(^+\) T cells. A virus neutralization assay showed that pORF2 evoked stronger recall virus-neutralizing (VN) antibody responses than the Cap protein on PCV2 challenge. Correspondingly, VN antibody kinetics coincided with those of Cap-specific IgG2a, but not with the kinetics of IgG and IgG1. Following virus challenge, real-time PCR and histopathological analysis confirmed that only low viral DNA loads and mild microscopic lesions appeared in pORF2-immunized mice. These findings indicate that CD8\(^+\) T cells and VN antibody responses correlating mainly with Cap-specific IgG2a play crucial roles in protecting against PCV2 infection, and that the protective immunity induced by the pORF2 plasmid is superior to that induced by the PCV2 Cap protein.

INTRODUCTION

Post-weaning multisystemic wasting syndrome (PMWS), first recorded in pigs in Western Canada in 1991, has been described in pigs from many regions of the world (Allan et al., 1998b; Allan & Ellis, 2000; Clark, 1997; Wen et al., 2005; Zhou et al., 2006). PMWS affects pigs of 5–12 weeks of age, with a morbidity of 5–30%; it is characterized by weight loss, dyspnoea and jaundice. Field and experimental evidence has revealed that PMWS-affected pigs may develop severe immunosuppression (Segales et al., 2004).

Porcine circovirus 2 (PCV2) has been identified as the primary aetiological agent of PMWS (Allan et al., 1998a, b; Allan & Ellis, 2000; Ellis et al., 1998; Fenaux et al., 2002; Meehan et al., 1998). PCV2 is a non-enveloped, single-stranded, circular DNA virus with a diameter of 17 nm (Tischer et al., 1982). The PCV2 genome comprises 1767 or 1768 nt and is assumed to have 11 potential open reading frames (ORF1–11; Hamel et al., 1998; Zhou et al., 2006). Previous studies have demonstrated that ORF1, -2 and -3 encode a 35.7 kDa replication (Rep) protein involved in virus replication (Mankertz et al., 1998), a 27.8 kDa capsid (Cap) protein involved in PCV2 immunogenicity (Mahe et al., 2000; Nawagitgul et al., 2000; Truong et al., 2001; Zhou et al., 2005a) and a protein involved in PCV2-induced apoptosis (Liu et al., 2005), respectively.

Immunization against PCV2 has been studied intensely and found to be the most effective strategy for protecting pigs against PCV2 infection. Based on comparison of the immunogenicity of the PCV2 Cap and Rep proteins, Blanchard et al. (2003) demonstrated that the ORF2-encoded Cap protein was the major immunogen, whilst the ORF1-encoded Rep protein was only weakly immunogenic. Kamstrup et al. (2004) subsequently investigated the potential of a DNA vaccine encoding the PCV2 Cap protein in mice and demonstrated the production of antibody. On the other hand, Fenaux et al. (2003, 2004) focused on a chimeric PCV1–PCV2, which was shown to induce specific antibody responses and protection against PCV2 in pigs. Recent studies on live virus vectors have shown that a recombinant pseudorabies virus (Ju et al., 2005; Song et al., 2007) and adenovirus (Wang et al., 2006, 2007) expressing Cap protein can elicit specific humoral and/or lymphocyte proliferation responses in mice and/or pigs, encouraging further studies of PCV2 vaccines.
However, the mechanisms underlying the immune response and protection against PCV2 have not yet been fully characterized. The purpose of this study was to characterize the protective immune response against PCV2 using a DNA plasmid expressing ORF2 (pORF2) and recombinant Cap protein as PCV2 DNA and subunit vaccines, respectively. Our data suggest that CD8+ T cells and recall virus-neutralizing (VN) antibody responses correlating with Cap-specific IgG2a may play important roles in developing protective immunity against PCV2 infection.

**METHODS**

**Cells, virus, protein and mice.** A PCV-free PK-15 cell line was maintained in minimal essential medium (Gibco) supplemented with 10% heat-inactivated fetal bovine serum (FBS; Gibco). The virulent PCV2 isolate HZ0201 was originally isolated from pigs with naturally occurring PMWS (Zhou et al., 2006) and serially passaged 15 times in PK-15 cells. The PCV2 Cap protein was generated as a subunit vaccine as described previously (Zhou et al., 2005a). Eight-week-old female BALB/c mice were purchased from Shanghai Laboratory Animal Center (Chinese Academy of Sciences, Shanghai, China) and raised in automatic extrusion-independent venting isolation cages (Fengshi Laboratory Animal Equipment Co.).

**Construction and preparation of an ORF2-based DNA vaccine.** The entire ORF2 was amplified from the genomic DNA of PCV2 isolate HZ0201 (GenBank accession no. AY188355) using specific forward (5'-GGGTTAAAGGCTTATCCTGCA-3') and reverse (5'-TATAGGTCATTGATTGTGTAAGG-3') primers, and was subcloned into the mammalian expression vector pcI-neo (Promega) to construct the recombinant expression plasmid pORF2. To determine the expression of Cap protein in eukaryotic cells, PCV-free PK-15 cells were transfected with pORF2 using Lipofectin reagent (Invitrogen). At 48 h post-transfection, the cells were fixed and examined using an indirect immunofluorescence assay (IFA) with murine monoclonal antibody (mAb) against Cap protein (Zhou et al., 2005a) and fluorescein isothiocyanate (FITC)-conjugated goat anti-mouse IgG (KPL, Kirkegaard and Perry Laboratories) as the primary and secondary antibodies, respectively. Finally, the pORF2 plasmid was purified using an EndoFree Plasmid Giga kit column (Qiagen) for use as a DNA vaccine.

**Experimental design and sample collection.** Eighty mice were divided randomly into eight groups of ten mice each. The mice in the four vaccine groups were injected intramuscularly in the quadriceps with 100 µg pORF2 plasmid or Cap protein prepared in 100 µl PBS as follows. The mice in the pORF2 and Cap groups received vaccination with pORF2 plasmid or Cap protein, respectively, three times every 2 weeks, whilst those in the pORF2/Cap or Cap/pORF2 group were primed with pORF2 plasmid (or Cap protein) and boosted with doses of Cap protein (or pORF2 plasmid) twice every 2 weeks. In the four control groups, the pcI-neo vector and crude lysate of E. coli strain BL21 transformed with pGEX-4T-1 were used as substitutes for pORF2 plasmid and Cap protein, respectively. After the first immunization, mouse serum samples were withdrawn from the retro-orbital sinus every 2 weeks until the end of the experiment for antibody detection and viremia evaluation. At 8 weeks after the first immunization (p.i.), five mice from each group were euthanized for flow cytometric analysis (FCM) and a lymphocyte proliferation assay (LPA). At 16 weeks p.i., the remaining five mice from each group were challenged intraperitoneally with 0.2 ml PCV2 inoculum (10^5.25 TCID50 ml^-1). Clinical signs in the challenged mice were recorded daily for 6 weeks, following which all mice were euthanized and their spleens collected for pathological analysis.

**Lymphocyte proliferation assay.** Proliferation of splenocytes in the immunized mice was determined using a 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) test as described previously (Zhou et al., 2005b). In brief, the spleens were excised aseptically from the mice at 8 weeks p.i. in order to prepare single-cell suspensions (4 × 10^5 cells ml^-1) in RPMI 1640 containing 5% FBS; the suspensions were applied to each well of a 96-well culture plate (100 µl per well). Wells containing no cells were used as blank controls. The PCV2 Cap protein diluted in RPMI 1640 with 5% FBS was then added at a final concentration of 1 µg ml^-1 (100 µl per well) to stimulate the splenocytes. After incubation at 37 °C in 5% CO2 for 48 h, 20 µl MTT (5 mg ml^-1; Sigma) was added to each well and the cells were incubated for 4 h. The cells were lysed by adding 100 µl lysis buffer (10% SDS, 0.01 M HCl) to each well. After incubation for 20 h, the absorbance of each well was measured at 570 nm. The stimulation index (SI) was calculated using the following formula: SI=(A_{vaccine}-A_{blank})- (A_{control} - A_{blank}).

**Flow cytometric analysis (FCM).** The cultured and stimulated splenocytes (10^6 cells) were resuspended in 50 µl PBS and incubated with 50 µl diluted (1:200) FITC-conjugated anti-mouse CD4 (L3T4; BD Biosciences) and R-phycocerythrin-conjugated anti-mouse CD8a (Ly-2; BD Biosciences) mAbs at a concentration of 0.5 µg per 10^6 cells in an ice bath. After 20 min incubation, the cells were washed and analysed using a BD-LSR cytometer using CellQuest software (BD Biosciences).

**Detection of Cap-specific IgG, IgG1 and IgG2a antibodies.** An indirect ELISA (Shang et al., 2008) was performed to detect the titres of total IgG, IgG1 and IgG2a antibodies against PCV2 Cap protein. In brief, 96-well plates (Nunc) were coated with 100 µl PCV2 Cap protein (1 µg ml^-1) in 0.05 M Tris/HCl (pH 8.5) and left at 4 °C overnight. The plates were then blocked with 5% skimmed milk, and 100 µl serially twofold-diluted mouse serum samples (lowest dilution 1:64) were added and incubated at 37 °C for 60 min. The bound antibodies were detected by horseradish peroxidase-conjugated goat anti-mouse IgG, IgG1 or IgG2a antibody (diluted 1:6000; Southern Biotechnology Associates). Tetramethylbenzidine (Sigma) was used as a chromogen for colour development and absorbance was measured at 450 nm. Antibody titres were defined as the reciprocal of the highest dilution of sample for which the absorbance was at least twice that of the control serum sample run on the same plate. The data were presented as the log2 value of the titre.

**Detection of PCV2-neutralizing antibodies.** A virus neutralization test was performed as described previously (Zhou et al., 2005a) with some modifications. In brief, the test sera were inactivated by heating at 56 °C for 30 min. An equal volume of PCV2 HZ0201 (10^6.0 TCID50 ml^-1) and serial twofold dilutions (1:20 to 1:20 480) of the sera were mixed and incubated at 37 °C for 1 h. The serum/virus mixture was added to 96-well microtitre plates containing semi-confluent monolayers of PCV-free PK-15 cells at 10 µl per well at a ratio of 1:10 using two wells per serum dilution. The plates were subsequently incubated at 37 °C for 48 h and finally screened by IFA as described above. The serum titres were determined as the reciprocal of the highest serum dilution resulting in ≥70% fluorescent focus reduction in the infected cell cultures viewed under a fluorescent microscope.

**Pathological analysis.** The spleens of mice were collected at 6 weeks post-challenge (p.c.) and processed using conventional histopathological methods. Briefly, the spleens were fixed in 10% neutral-buffered formalin solution, sectioned and stained with haematoxylin and eosin (H&E). Microscopic changes were
determined by comparing the splenic tissues of the challenged mice with those of the control-group mice. The intensity of lesions was estimated as the frequency of abnormal spleen follicles, which is the ratio between the number of the follicles with lymphoid depletion and histiocytic infiltration and the total number of follicles counted in the spleen section of each mouse.

**Quantitative real-time PCR for evaluation of viraemia.** Viral DNA levels in the mouse serum samples collected after PCV2 challenge were determined using a quantitative real-time PCR. Total DNA was extracted from 10 μl serum by using a UNIQ-10 virus DNA minikit according to the manufacturer’s instructions (Sangon). A forward (5'-TGTAGTATTCAAGGGCACAGGC-3') and a reverse (5'-CGGATATCTATCAAGGCACCAC-3') primer were used to amplify a 130 bp fragment from the ORF2 of PCV2. The PCR contained a final concentration of 1× SYBR Premix Ex Taq (TaKaRa), 0.2 μM each primer and DNA equivalent to that of 1μl serum as template. All reactions were carried out in duplicate on a RealPlex4 (Eppendorf). The program consisted of one cycle at 95 °C for 1 min and 40 cycles at 95 °C for 5 s and 60 °C for 20 s, and was followed by a melting curve analysis to analyse specificity. Serial dilutions of plasmid pORF2 were used to obtain a standard curve. The numbers of virus copies for each sample were presented as the mean value of duplicate reactions. The detection limit of this assay was 10³ copies ml⁻¹.

**Statistical analysis.** Statistical analysis was performed by one-way analysis of variance using SPSS version 12.0 (SPSS). Results were considered to be statistically significant for P<0.05.

**RESULTS**

**In vitro expression of PCV2 Cap protein in PK-15 cells**

The recombinant plasmid pORF2 was identified using PCR and restriction enzyme digestion and was confirmed by DNA sequencing. *In vitro* expression of Cap protein was analysed by transient transfection followed by an IFA. PK-15 cells transfected with pORF2 were recognized by mAb to Cap at 48 h post-transfection and the expressed Cap protein was found to localize in the nuclei of cells (Fig. 1), as observed in PCV2-infected cells (Allan et al., 1998b), suggesting that the mammalian expression vector pORF2 mimics PCV2 expression of Cap protein *in vivo.*

**Cap-induced cellular immune responses**

Mice splenocytes were collected at 8 weeks p.i. and their lymphoproliferative responses to Cap protein were assayed (Table 1). The SI values of all the vaccinated mice were significantly higher than those of the control mice (P<0.01). Although mice in the Cap group exhibited the strongest responses to Cap protein, there was no significant difference among the responses of mice in the various vaccine groups (P>0.05). The proportions of CD4⁺ and CD8⁺ cells in the stimulated splenocytes were determined by FCAM. As shown in Table 1, significant upregulation of CD4⁺ cells was elicited in all of the vaccine groups compared with the control group (P<0.01). With regard to the expression of CD8⁺ cells, only the pORF2 (P<0.01) and pORF2/Cap (P<0.05) groups showed significant increases in CD8⁺ cells. These data indicated that the pORF2 plasmid is superior to Cap protein in inducing CD8⁺ cells, whilst both had a comparable capability to trigger CD4⁺ cells.

**Total IgG and isotypes of serum antibody against PCV2 Cap protein**

The titres for total IgG against PCV2 Cap protein in the vaccinated mice were determined using an indirect ELISA. All mice primed with protein in the Cap and Cap/pORF2 groups seroconverted at 2 weeks p.i., whilst those in the pORF2/Cap and pORF2 groups seroconverted at 4 and 10 weeks p.i., respectively. As shown in Fig. 2, the Cap and pORF2/Cap protocols induced higher IgG titres with peaks of 18.2±0.8 and 17.0±1.7 log₂ at 10 and 12 weeks p.i., respectively, compared with that of the pORF2 (14.8±1.3 log₂) and Cap/pORF2 (15.3±2.2 log₂) vaccines. A notable decrease in the antibody titre was observed at 8 weeks p.i. in the Cap/pORF2 group mice (Fig. 2). These data clearly showed that the Cap protein elicited more effective antibody responses in ELISA than the pORF2 plasmid.

We analysed the IgG1/IgG2a isotypes against PCV2 Cap protein in order to determine the profile of antibody responses induced by different protocols. The pORF2 plasmid stimulated significantly higher IgG2a antibodies

**Table 1.** PCV2 Cap-specific lymphoproliferative response and FCM analysis of mice splenocytes

Significant differences between the vaccine and control groups are indicated: *, P<0.01; †, P<0.05.

**Fig. 1.** *In vitro* expression of PCV2 Cap protein. PCV-free PK-15 cells were transfected with pORF2 (a) or pCI-neo (b), fixed at 48 h post-transfection and detected using an IFA with mAb against Cap protein.
than IgG1 from 10 to 16 weeks p.i. ($P<0.05$), with a peak IgG2a titre of $14.0 \pm 1.5 \log_2$ at 10 weeks (Fig. 3a). In contrast, the Cap protein induced significantly higher IgG1 levels than IgG2a levels from 2 to 16 weeks p.i. ($P<0.01$), with a peak IgG1 titre of $17.8 \pm 0.8 \log_2$ at 6 weeks (Fig. 3b).

With regard to heterologous vaccinations, peak IgG1 ($16.0 \pm 0.8 \log_2$) and IgG2a ($14.8 \pm 2.1 \log_2$) titres appeared at 12 weeks p.i. in the pORF2/Cap group (Fig. 3d), whilst peak IgG1 ($13.5 \pm 1.7 \log_2$) and IgG2a ($14.3 \pm 1.0 \log_2$) titres appeared at 16 and 14 weeks, respectively, in the Cap/pORF2 group (Fig. 3c). Statistically, the IgG1 titres were significantly higher than those of IgG2a at 2–4 weeks p.i. for Cap/pORF2 and at 4–8 weeks p.i. for pORF2/Cap ($P<0.05$); they subsequently became non-significant (Fig. 3c, d). These results suggested that immunization with the pORF2 plasmid or Cap protein alone induced Th1 or Th2 responses, respectively; based on this, IgG2a was produced as a consequence of Th1 cell activation and IgG1 as a result of Th2 cell activation (Mosmann & Coffman, 1989b).

**VN antibody to PCV2 and its correlation with IgG isotypes**

The ability of mice sera to neutralize PCV2 infection was detected using a virus neutralization test together with an ELISA. Prior to virus challenge, no detectable VN antibodies were observed in mice in any group (data not shown). After challenging the mice with PCV2 strain HZ0201 at 16 weeks p.i., strong recall VN antibody responses were observed in the pORF2, Cap/pORF2 and pORF2/Cap groups at 2 weeks p.c., with a seropositivity rate of 100% and mean titres of 640, 805 and 960, respectively (Fig. 4). The VN antibody titres in the pORF2 and pORF2/Cap groups increased steadily and peaked at 6 weeks p.c., whereas those in the Cap/pORF2 group peaked at 2 weeks p.c. and then decreased gradually (Fig. 4). In contrast, mice in the Cap group exhibited
weak recall responses with mean VN antibody titres of 16, 28 and 16 at 2–6 weeks p.c. For PCV2-infected control mice, the VN antibody titres were only detected in a few mice at 4 (one mouse) and 6 (two mice) weeks p.c. Statistically, the VN antibody titres of the pORF2 and pORF2/Cap groups were higher than those in the Cap group at 2–6 weeks p.c. (P < 0.05) (Fig. 4). These results showed that the protocol using the plasmid was more effective than that with the Cap protein alone in inducing recall PCV2-neutralizing antibody responses in mice.

To investigate the relationship of VN antibodies and IgG isotypes, we compared the different antibody titres following virus challenge. At 2–6 weeks p.c., the Cap group mice exhibited higher IgG and IgG1 (P < 0.05) antibodies than the pORF2 group mice, whilst the pORF2 group mice presented higher VN (P < 0.05) and IgG2a antibodies than the Cap group mice (data not shown), implicating a probable correlation between the IgG2a and VN antibodies. We then analysed the antibody titres in individual mice. As shown in Table 2, mouse no. 12 with a VN titre of 640, whilst IgG2a titre of 15 log2 generated a VN titre of 640, whilst individual mice. As shown in Table 2, mouse no. 12 with a VN antibodies. We then analysed the antibody titres in Implicating a probable correlation between the IgG2a and antibodies than the Cap group mice (data not shown), P group mice presented higher VN (P < 0.05), whilst the pORF2 group showed the lowest VN antibody titres of the pORF2 and Cap groups at 2 weeks p.c.

*Mice were challenged at 16 weeks p.i.
†Cap-specific IgG1 and IgG2a titres were detected by ELISA and expressed as log2 values.
‡VN activity was analysed in a twofold dilution series starting at 1 : 20.

In the challenged control mice was 38.6 ± 5.8 %, whereas that of the microscopic lesions in the immunized mice was significantly less compared with the control (P < 0.01), with mean values of 10.6 ± 8.5 % for the pORF2 group, 24.7 ± 7.2 % for the Cap group, 13.0 ± 8.4 % for the Cap/pORF2 group and 9.7 ± 7.0 % for the pORF2/Cap group (Fig. 5b). The frequency of lesions was significantly higher for the Cap group compared with the other vaccine groups (P < 0.01).

DISCUSSION

PCV2 is the primary aetiologal agent of PMWS. In this study, we characterized the protective immunity of mice against PCV2. Previous studies have reported mice as a model for PCV2 infection (Kuipe et al., 2001; Liu et al., 2006). Although two reports (Quintana et al., 2002; Wang et al., 2006) have described that PCV2 inoculation failed to induce murine lesions, this difference was considered to be related to inoculum dosage and route of administration (Quintana et al., 2002). In the present study, intraperitoneal inoculation of PCV2 successfully produced lesions
in mice. Furthermore, we chose changes in the spleen as the criteria of pathological analysis, as these are a distinct feature of PCV2 infection. The observed abnormal follicles with lymphocyte depletion and histiocyte infiltration resembled lesions found in PMWS-affected pigs (Chianini et al., 2003; Sarli et al., 2001), as well as those in PCV2-inoculated mice (Kiupel et al., 2001; Liu et al., 2006); therefore, mice were deemed suitable models for this study.

A recent in vivo study reported that B cells may be the primary site of PCV2 replication during early infection (Yu et al., 2007), although in vitro studies have shown that PCV2 can replicate in primary porcine hepatocytes (Hirai et al., 2006) and that PCV2 particles can persist without replication in dendritic cells and porcine alveolar macrophages as well as in monocytes (Gilpin et al., 2003; Vincent et al., 2003). Thus, the target cells for PCV2 replication have not been clearly identified thus far. With regard to PCV2 immunization, no data regarding lymphocyte subsets in cellular immune responses have been recorded recently, although ORF2-based vaccines against PCV2 have been reported previously (Blanchard et al., 2003; Fan et al., 2008; Fenaux et al., 2003; Fig. 5. Microscopic lesions in the spleens of PCV2-challenged mice. (a) Mice were challenged with the virulent PCV2 at 16 weeks p.i. and the presence of splenic lesions was determined by conventional methods of histopathology at 6 weeks p.c. (i) No abnormal follicles were seen in the spleen of unchallenged mice. (ii) Significant depletion of lymphocytes within follicles (arrows) was observed in the spleen of PCV2-inoculated mice. (iii) Infiltration of histiocytes in the splenic follicle of a PCV2-inoculated mouse (arrows). (iv) Apoptotic cells (arrows) in the spleen follicle of a PCV2-inoculated mouse. (v) Mild lymphocyte depletion within a follicle (arrow) in the spleen of a Cap-immunized mouse inoculated with virulent PCV2. Cells were stained with H&E. Bars, 80 μm (i, ii, v); 20 μm (iii, iv).

(b) Frequencies of abnormal spleen follicles at 6 weeks p.c. Shared letters above columns indicate no significant difference (P>0.05), whilst different letters indicate significant differences among the groups (P<0.05) (n=5).

Table 3. Viraemia in mouse serum measured by quantitative PCR

Different superscripts within columns represent significantly different PCV2 loads for each week p.c. (P<0.05). A load value of 0 is equal to <10³ copies ml⁻¹ (the threshold of sensitivity of the quantitative PCR).

Although the ORF2-based DNA and subunit vaccines were equally efficient in eliciting lymphoproliferative activity and splenocyte phenotypes induced by different immunization protocols. Although the ORF2-based DNA and subunit vaccines were equally efficient in eliciting lymphoproliferative responses and CD4+ cells, the pORF2 plasmid was superior to the Cap protein in inducing CD8+ cells. Correspondingly, protocols using pORF2 exhibited a higher efficacy than those with subunit vaccine alone in the protection assay (Table 3, Fig. 5). These results imply that CD8+ cells, which are associated with virus-specific cytotoxicity, may contribute to protective immunity against PCV2 infection. Indeed, cytotoxic T-lymphocyte responses are considered to be the effector mechanisms required for protective immunity of a variety of intracellular infections, such as malaria (Doolan et al., 1996), human immunodeficiency virus infection (Ogg et al., 1998) and simian immunodeficiency virus infection (Schmitz et al., 1999).

PCV2 Cap protein is related to the induction of PCV2-neutralizing antibody (McNeilly et al., 2001; Zhou et al., 2005a). To date, the protective mechanism of humoral immunity against PCV2 infection has not been fully characterized. It is generally accepted that PCV2-specific antibodies are associated with protection, as field evidence suggests that the decrease in antibodies contributes to the development of PMWS (Allan & Ellis, 2000; Allan et al., 1998b; McIntosh et al., 2006). However, in some cases, the serum antibody level does not appear to influence PMWS occurrence (Carasova et al., 2007; McIntosh et al., 2006). During the PCV2 infection period in this experiment, the IgG2a antibody in the pORF2-immunized mice exhibited higher titres than in the Cap-vaccinated mice (Fig. 3). Correspondingly, we found that the tendency of VN antibody to protect against PCV2 infection coincided with Cap-specific IgG2a but not with total IgG or IgG1 (Figs 3 and 4, Table 2). Therefore, it is reasonable to suggest that VN antibody against PCV2 is composed mainly of IgG2a against Cap protein, and that this Cap-specific neutralizing IgG2a antibody plays an important role in protecting against PCV2 infection. In fact, VN antibodies against dengue virus (Simmons et al., 2001) and herpes simplex virus type 1 (McKendall & Woo, 1988) have also been shown to comprise primarily IgG2a antibody in mice. A recent study reported that recombinant adenovirus expressing the Cap protein generated VN antibody titres ranging from 1:8 to 1:17 in mice (Wang et al., 2006), and all plasmids encoding Cap protein with different subcellular localizations induced VN antibody titres of <1:10 in mice (Fan et al., 2008). Surprisingly, in our experiment, no VN antibody against PCV2 was detected in the immunized mice before virus challenge. This may have been due to the threshold of the virus neutralization test used in our study, which failed to detect VN titres of <1:20. Therefore, a method for improving the induction of VN antibody against PCV2 requires further study.
