IMPAIRMENT BY BACTEROIDES SPECIES OF OPSONISATION AND PHAGOCYTOSIS OF ENTEROBACTERIA

G. R. JONES AND C. G. GEMMELL

Department of Bacteriology, Medical School, University of Glasgow Royal Infirmary, Glasgow G4 0SF

SUMMARY. The ability of human polymorphonuclear leucocytes to phagocytose and kill Proteus mirabilis was impaired in vitro when the human serum, used to opsonise the target bacteria, was pretreated with cultures of various Bacteroides species. Live and dead, either heat-killed or clindamycin-treated, bacteroides cells elicited the same phenomenon. When bacteroides-treated serum was used to opsonise different Proteus species, the subsequent uptake of all strains by polymorphonuclear leucocytes was inhibited, whereas bacteroides-treated serum inhibited the uptake of some but not all of the test strains of Escherichia coli. The opsonic activity of untreated human serum was reduced when the classical complement pathway was inhibited by ethyleneglycol-bis-(p-aminoethyl ether)N,N'-tetra-acetic acid (EGTA); subsequent treatment with bacteroides did not further reduce the opsonic activity of the serum for P. mirabilis.

INTRODUCTION

The susceptibility of pathogenic micro-organisms to phagocytosis by polymorphonuclear leucocytes (PMNL) and macrophages is important in determining the outcome of the host-parasite relationship. Interference with normal phagocytic processes by bacterial products can often determine the severity and extent of infection. Individual bacteria can elaborate substances that interfere with phagocytosis (for review see Quie, Giebink and Peterson, 1981).

However, the effect of cells of one bacterial species on the phagocytosis of another was not studied experimentally until Ingham et al. (1977) reported that some Bacteroides species are capable of inhibiting the phagocytic killing of various bacteria by human PMNL in vitro. This inhibition depended on a low Eh and required at least 10³ anaerobes/ml in the phagocytic system. Facultative anaerobes such as Escherichia coli did not impair phagocytosis of Proteus mirabilis.

Tofte et al. (1980) found that the uptake of E. coli by PMNL was markedly inhibited in the presence of Bacteroides fragilis or B. melaninogenicus, but conversely E. coli did not significantly affect the uptake of either anaerobe. These workers suggested

Received 27 Nov. 1981; accepted 14 Dec. 1981.
that the test bacteroides were either more efficiently or more rapidly opsonised than *E. coli* and therefore deprived *E. coli* of serum opsonins needed for efficient phagocytosis by PMNL.

The present study was undertaken to determine the extent of the inhibition of phagocytosis by bacteroides. Some of the factors involved were investigated by measuring the uptake of radiolabelled bacteria and the killing of *P. mirabilis* and *E. coli* by PMNL in the presence or absence of bacteroides organisms.

**Materials and methods**

*Bacterial strains.* *B. melaninogenicus* strain no. 4 and *Proteus mirabilis* strain NGH were kindly provided by Dr H.R. Ingham, General Hospital, Newcastle upon Tyne, NE4 6BE. Twelve strains of bacteroides and 28 enterobacteria were randomly chosen from fresh clinical isolates obtained in the Bacteriology Department, Royal Infirmary, Glasgow G4 0SF. Identification of the *Bacteroides* species was based on the method of Duerden et al. (1980), and of the coliforms by the API 20E system (API Laboratory Products, Grafton Way, Basingstoke, Hants RG22 6HY.

The species included in this study were *E. coli* (14 strains), *P. vulgaris* (3 strains), *P. mirabilis* (7 strains), *P. morgani* (4 strains), *B. melaninogenicus* (6 strains), *B. fragilis* (5 strains) and *B. thetaotaomicron* and *B. vulgatus* (1 strain each).

*Culture of bacteroides.* Each isolate was cultured in a medium consisting of Cooked Meat Particles (Difco) reconstituted in Brain Heart Infusion Broth (Difco) to which menadione (1 µg/ml, Sigma Chemical Company, St Louis) and haemin (5 µg/ml, Sigma) were added. Cultures were incubated for 48 h at 37°C and used in the experiments without subsequent treatment unless otherwise stated.

*Culture and radiolabelling of the enterobacteria.* The *Proteus* and *E. coli* isolates were cultured overnight in 20 ml of Mueller-Hinton Broth (Oxoid) containing 3H-thymidine (specific activity 25 Ci/mmol; Radiochemical Centre, Amersham, Bucks HP7 9LL) at a final concentration of 10 µCi/ml broth. After incubation, the bacteria were centrifuged at 3000 g for 10 min and washed three times with 0.85% saline before use.

*Opsonisation.* Fresh human serum obtained from the Haematology Department, Glasgow Royal Infirmary, was divided into 5-ml portions and stored at −70°C before use. For opsonisation, serum was diluted to 50% with Hanks’s balanced salt solution containing 0.1% gelatin (gel-HBSS). The washed radiolabelled test bacterial suspension was diluted with saline to contain approximately 5 × 10⁷ organisms/ml by spectrophotometric determination. Equal volumes of the standardised bacterial suspension and 50% serum in gel-HBSS were mixed, incubated at 37°C for 15 min in an orbital incubator (shaking speed 150 rpm) and then centrifuged at 3000 g for 10 min. The bacterial pellet was resuspended in gel-HBSS to its original volume.

In some experiments the human serum was heat treated at 56°C for 30 min to inactivate complement before opsonisation. The heated serum failed to opsonise *E. coli* or *Proteus* organisms and this was assumed to indicate that little or no antibody with opsonic activity remained. Serum complement activation via the classical pathway was inhibited by addition of 0.1 ml of 0.1 M ethylene glycol-bis-(β-aminoethyl-ether) N,N'-tetra-acetic acid (EGTA, Sigma) to 0.9 ml of serum and held at room temperature for 30 min. Further dilutions of the chelated serum were then made in 0.85% saline.

*Leucocyte preparation.* Venous blood was obtained from individual healthy volunteers; it was heparinised (10 U heparin/ml blood) and mixed with dextran (mol. wt 150 000; 6% w/v in 0.85% saline; Fisons Limited, Loughborough, Leics LE11 0RG) in a blood : dextran solution ratio of 4 : 1. Sedimentation of erythrocytes was allowed for 20–30 min. The supernatant fluid and the cells at the interface were removed and centrifuged at 100 g for 5 min. The deposit was suspended in 0.87% ammonium chloride (BDH Chemicals Ltd, Poole, Dorset BH12 4NN) and mixed gently for 15–20 min to allow lysis of the erythrocytes. After centrifugation at 100 g for 5 min, the leucocytes were suspended in gel-HBSS and adjusted to contain approximately 5 × 10⁶ PMNL/ml as determined with a haemocytometer.
IMPAIRMENT OF PHAGOCYTOSIS BY BACTEROIDES

Uptake of radiolabelled bacteria. The method of Verhoef, Peterson and Quie (1977) was followed. For each phagocytosis mixture, duplicate test vials containing 0.1 ml of radiolabelled, opsonised bacteria and 0.1 ml of the leucocyte suspension were incubated for 45 min at 37°C in an orbital incubator (shaking speed 150 rpm). Duplicate controls containing gel-HBSS in place of the leucocyte suspension were included. After incubation, 3 ml of scintillation fluid (Aqualuma, Lumac Systems AG, Basle) was added to one of the test and to one of the control vials. Measurement of radioactivity in these vials provided an estimate of the total number of bacteria present in each phagocytic mixture. To the other test and control vial, 3 ml of ice-cold phosphate-buffered saline (PBS), pH 7.4, was added, the vials were centrifuged at 100 g for 5 min to sediment the PMNL and the supernatant fluid was discarded. These vials were given two more washes with PBS and 3 ml of scintillation fluid was then added to each vial. Measurement of radioactivity in these vials provided an estimate of the number of ingested bacteria present in each phagocytic mixture. The counts per minute of the contents of each vial were determined in a liquid scintillation counter (1210 Ultrobeta, LKB Instruments, 232 Addington Way, S. Croydon, Surrey CR2 8YD). The percentage uptake of labelled bacteria was calculated as follows:

\[
\frac{\text{cpm: centrifuged mixture containing PMNL}}{\text{cpm: uncentrifuged mixture containing PMNL}} \times 100.
\]

This value was corrected by subtracting the corresponding value obtained from the counts recorded for the vials that did not contain PMNL.

Measurement of phagocytosis. Phagocytosis and killing of bacteria by leucocytes was estimated by the method of Ingham et al. (1977). Briefly, 0.5 ml of leucocyte suspension, 0.1 ml of serum (undiluted), 0.1 ml of coliform suspension, 0.1 ml of bacteroides suspension (containing \(10^8-10^9\) organisms/ml of Robertson's cooked meat medium) and 0.2 ml of gel-HBSS were incubated aerobically at 37°C for up to 5 h in an orbital incubator. Controls without serum, leucocytes or bacteroides culture were included, with gel-HBSS substituted in each case. After incubation, tenfold dilutions of the mixtures were made in distilled water and 20-μl amounts of each dilution were inoculated onto agar plates in duplicate. Gentamicin blood-agar plates, containing gentamicin 50 μg/ml, to inhibit the growth of Proteus and E. coli, were used for the anaerobes, and cystine lactose electrolyte-deficient medium (CLED, CM 301 Oxoid) was used for the coliforms. After incubation, the viable count was calculated according to the method of Miles, Misra and Irwin (1938).

Statistical analysis of the results was performed by the Mann-Whitney U test.

RESULTS

Factors affecting uptake of labelled bacteria

The mean uptake of radiolabelled opsonised cells of P. mirabilis strain NGH by PMNL was 81% compared with 3% for unopsonised P. mirabilis cells (fig. 1). The uptake of this strain was markedly reduced (p < 0.001) when the bacteria were opsonised with serum pretreated with B. melaninogenicus strain 4, and less markedly but still significantly reduced when opsonised with untreated serum in the presence of B. melaninogenicus cells.

In tests with several different isolates of Proteus and E. coli (see fig. 2), pretreatment of the serum with B. melaninogenicus strain 4 significantly inhibited (p < 0.001) the uptake of most (10/14) of the Proteus isolates. The uptake of E. coli isolates was more varied; the uptake of seven of the 14 isolates was inhibited by more than 50% but with five isolates there was little or no change in uptake.

Pretreatment of the serum with any of the 13 isolates of Bacteroides inhibited the uptake of P. mirabilis strain NGH by at least 50% (table I). When E. coli was substituted for Bacteroides there was little change in the uptake of the proteus by
PMNL. Similarly, if serum treated with *E. coli* was used for opsonisation or if pre-opsonised *P. mirabilis* strain NGH cells were incubated with *E. coli*, there was no alteration in the uptake of the radio-labelled bacteria by PMNL (*p* > 0.005) (fig. 3). When simultaneous opsonisation of *P. mirabilis* strain NGH and *E. coli* was carried out, the mean uptake of the proteus was reduced from 80% to 60%, but this difference was not statistically significant (*p* > 0.05).

When culture filtrates of *B. melaninogenicus* strain 4 were incubated with normal human serum before opsonisation of *P. mirabilis* strain NGH, the uptake of *P. mirabilis* NGH was significantly reduced (*p* < 0.001) indicating that a cell-free component in the culture supernate might be involved (fig. 4). Similarly, a heat-killed *B. melaninogenicus* culture and a suspension of *B. melaninogenicus* strain 4 in saline containing 1% ascorbic acid impaired the uptake of *P. mirabilis* strain NGH (*p* < 0.001). To exclude the possibility that the bacteria *per se* might be causing a direct effect on the PMNL, PMNL were preincubated with either unopsonised *B. melaninogenicus* strain 4, *P. mirabilis* strain NGH or *E. coli*, and these PMNL showed normal uptake of opsonised *P. mirabilis* (table II).
IMPAIRMENT OF PHAGOCYTOSIS BY BACTEROIDES

Fig. 2—Frequency of uptake by polymorphonuclear leucocytes (PMNL) of various isolates of Proteus (7 strains of P. mirabilis, 3 of P. vulgaris, 4 of P. morgani) and 14 isolates of E. coli opsonised with serum pretreated with B. melaninogenicus strain 4. Values are expressed as a percentage of the corresponding uptake of each isolate opsonised with normal human serum. A = Proteus; B = E. coli.

* Normal serum opsonisation allowed 75%-100% uptake by polymorphonuclear leucocytes (PMNL).

**Fig. 3**—Effect of *E. coli* on the uptake of *P. mirabilis* strain NGH by polymorphonuclear leucocytes (PMNL). **A** = opsonised; **B** = non-opsonised; **C** = opsonised in presence of *E. coli*; **D** = opsonised with serum previously treated with *E. coli*; **E** = opsonised and subsequently incubated with *E. coli*. Each result represents the mean and range of at least three experiments.
FIG. 4—Effect of heat-killed \textit{B. melaninogenicus} strain 4, \textit{B. melaninogenicus} strain 4 culture filtrate, and a suspension of \textit{B. melaninogenicus} strain 4 in saline containing 1\% ascorbic acid on the uptake by PMNL of \textit{P. mirabilis} strain NGH opsonised with serum treated with these preparations. \(A\) = opsonised; \(B\) = opsonised with serum treated with \textit{B. melaninogenicus} strain 4 culture; \(C\) = opsonised with serum treated with \textit{B. melaninogenicus} strain 4 culture filtrate; \(D\) = opsonised with a heat-killed culture of \textit{B. melaninogenicus} strain 4; \(E\) = opsonised with serum treated with \textit{B. melaninogenicus} strain 4 suspended in saline containing 1\% ascorbic acid. Each result represents the mean and range of at least three experiments.

When serum treated with EGTA to inhibit the classical complement pathway was used to opsonise \textit{P. mirabilis} strain NGH, the mean uptake of bacteria was reduced from 88\% to 30\% (fig. 5). Treatment of EGTA-treated serum with \textit{B. melaninogenicus} strain 4 before the opsonisation of \textit{P. mirabilis} strain NGH resulted in a mean uptake of 19\% by PMNL. This is comparable with a 24\% uptake when normal serum pretreated with \textit{B. melaninogenicus} strain 4 was used for opsonisation.

\textbf{Effect of \textit{B. melaninogenicus} on phagocytic killing}

In these studies the assay system of Ingham \textit{et al.} (1977) was used to measure the efficiency of bacterial killing by PMNL in the presence or absence of other bacteria. The susceptibility of \textit{P. mirabilis} strain NGH was measured over a 5-h period at 37\degree C. Viable counts taken at this time showed that \textit{P. mirabilis} strain NGH was markedly

† Inhibitory index is the ratio of the viable count at 5 h of *E. coli* or *P. mirabilis* in the presence of *B. melaninogenicus* to that obtained in the absence of proteus organisms.

occurred when *B. melaninogenicus* strain 4 was present. In contrast *E. coli* caused less inhibition of phagocytosis (inhibitory index: 54); most of the added bacteria were phagocytosed and killed. The number of viable *B. melaninogenicus* strain 4 remained virtually constant (5×10⁷ bacteria/ml of phagocytosis mixture) throughout. Neither killing *B. melaninogenicus* strain 4 by heat (100°C for 10 min) nor clindamycin (50 μg/ml culture) affected its ability to impair phagocytosis of *P. mirabilis* by PMNL.

**DISCUSSION**

These results confirm and extend the findings of Ingham et al. (1977) who reported the inhibition of phagocytic killing of various bacteria by *Bacteroides* species. The inhibition probably results solely from impairment of the phagocytic ingestion of bacteria.

The phagocytic uptake of all the *Proteus* strains tested was markedly impaired in contrast to that of some of the *E. coli* strains. The latter could be divided into those whose uptake by PMNL was inhibited by more than 50% or by less than 50% by *Bacteroides*. This variation may be due to differences in surface structures. Tofte et al. (1980) investigated only one strain of *E. coli* and found that its uptake by PMNL was inhibited by *B. melaninogenicus* and by *B. fragilis*.

Ingham et al. (1977) suggested that complement was unlikely to be the sole serum component affected by bacteroides treatment of serum. The present studies support the theory of Tofte et al. (1980) that competition for serum opsonins is the basis for the observed impairment of phagocytosis. Chelation of serum with EGTA to inhibit the classical pathway of complement reduced the uptake of *P. mirabilis* by PMNL but did not alter the reduced uptake that followed opsonisation with bacteroides-treated serum. Thus it appears that the bacteroides cells do not owe their activity to the impairment of the alternative complement pathway but to an action on the classical pathway. Preliminary experiments suggest that levels of C3 are similarly reduced by 20–30% when serum is treated with representative strains of *Bacteroides* or *Proteus* or *E. coli*. However, more analysis of the biological activity of each of the initial complement components is necessary to determine the precise locus affected by the bacteroides cells.

The cell concentration and *Eh* of the bacteroides culture appeared to be important
in the impairment of opsonic activity of human serum. Bacteria harvested and washed in saline lost their biological activity, whereas resuspension in a medium with a low Eh such as saline containing 1% ascorbic acid or fresh culture medium (Robertson's cooked meat) restored their activity; these findings agree with those of Ingham et al. (1977). One or two batches of undiluted cooked-meat medium impaired opsonisation and phagocytosis of Proteus species per se but we were unable to determine the factor responsible; on dilution significant inhibitory activity was not detectable. At least $10^5$ bacteroides/ml of human serum appeared to be necessary to cause significant impairment of opsonic activity.

Phagocytic uptake, measured over 45 min at 37°C, of P. mirabilis by PMNL in the presence or absence of bacteroides cells showed significant differences that were further amplified when the killing rates were monitored over 5 h. Although significant impairment of killing of Proteus was detectable even at 1 h, the number of viable bacteroides did not decline over the 5-h period; this suggests that little or no phagocytosis of bacteroides occurred in these conditions.

We have shown that there is competition between different bacterial species for serum opsonins and subsequent phagocytic uptake and killing by PMNL. Whether such a process might also take place in vivo is open to question. Reznikov, Finlay-Jones and McDonald (1981) studied the clearance of E. coli from the peritoneal cavity of mice in the presence or absence of B. fragilis. Even at an anaerobe:coliform ratio of 80:1 there was no impairment of the rate of clearing of E. coli from the mouse peritoneum; both organisms were cleared at the same rate. It is unlikely that serum interactions with bacteria and subsequent phagocytosis by PMNL in vitro and in vivo are directly comparable. Accordingly, we are now extending these studies in an investigation of phagocytic activity within abscesses experimentally induced by the method of Joiner et al. (1980).

We are grateful for the skilled technical assistance of Mr R. McNaught.

ADDENDUM

Since this paper was submitted for publication Ingham et al. (1981) have reported that interaction of bacteroides cells with human serum can inhibit intracellular killing but not ingestion of P. mirabilis. The results of the present study indicate that ingestion and killing are inhibited. The reasons for this difference are not clear but may be related to the times of sampling used in the two studies. Ingham et al. (1981) studied phagocytosis after incubation for 5 h whereas a 45-min incubation period was used in the present study. A reduced rate of uptake of radiolabelled proteus cells was evident at this time, and the killing of Proteus spp. became impaired within 1–2 h.
