PATHOGENIC MECHANISMS

Bone resorbing activity of surface-associated material from *Actinobacillus actinomycetemcomitans* and *Eikenella corrodens*

Summary. The results of this study demonstrate that saline extracted surface-associated material (SAM) of *Actinobacillus actinomycetemcomitans* and *Eikenella corrodens* stimulates bone resorption at picomolar concentrations. Various inhibitors of known osteolytic mediators—indomethacin, interleukin-1 receptor antagonist (IL-1ra) and a neutralising antibody to murine tumour necrosis factor (TNF)α—were tested to determine the mechanism of action of these SAMs. Bone resorption induced by SAM from *E. corrodens* was slightly inhibited by indomethacin and almost completely inhibited by blocking the action of TNFα; that from *A. actinomycetemcomitans* was not significantly affected by either of these inhibitors.

Introduction

Periodontal disease (PD) is the commonest chronic inflammatory disease afflicting man, and the destruction of alveolar bone is the most severe consequence of this disease. Although the stimulus that promotes bone breakdown in PD is still unresolved, it is likely that bacterial components which can penetrate into the periodontal tissues are involved. Bacterial lipo-polysaccharide (LPS) appears to be of prime importance but surface-associated material (SAM) from *Actinobacillus actinomycetemcomitans* does not contain LPS and is a more potent stimulator of bone resorption *in vitro* and significantly more active, on a dry weight basis, than LPS from the same organism. The ready solubility of this SAM coupled with its potent osteolytic activity supports the view that it may be a major factor in bone resorption in PD. In this study, the capacity of SAM from *A. actinomycetemcomitans* and *Eikenella corrodens* to induce bone resorption *in vitro* have been compared by the murine calvarial bone resorption assay. The mechanism by which the SAM produces bone breakdown has been investigated with various inhibitors and antagonists of the major osteolytic mediators believed to be active in pathological bone remodelling.

Materials and methods

**Extraction of bacterial SAM**

*A. actinomycetemcomitans* strain Y4 was grown at 37°C on Brain Heart Infusion Agar (Oxoid) under anaerobic conditions (Gas Pak System, Oxoid). *E. corrodens* NCTC 10596 was grown at 37°C under anaerobic conditions on a medium consisting of Brain Heart Infusion Agar (Oxoid) supplemented with (L) cysteine-HCl 0.375 g, haemin 0.25 g and menadione 0.05 g (all from BDH). Bacteria were grown on solid media in an effort to enhance production of extracellular polymers. After 3-4 days, all cultures were inspected visually for contamination, stained with Gram’s stain, removed from the plates with sterile saline and then centrifuged at 30000 g for 30 min at 4°C. The washing procedure was repeated, the cells were lyophilised and the SAM was extracted as described previously. Briefly, the cells were stirred gently in sterile saline at 4°C for 1 h and then sedimented by centrifugation. This process was repeated twice and the combined aqueous phases were pooled. The SAM was precipitated by the addition of acetone at -20°C, collected by centrifugation, dissolved in saline, dialysed against distilled water in benzoylated dialysis tubing with a mol.-wt cut-off of 2 kDa, and then lyophilised. This crude material was used in the subsequent studies. Every attempt was
made to ensure that endotoxin contamination during extraction was kept to a minimum. The protein content of the precipitated SAM was determined by the method of Lowry\(^3\) with bovine serum albumin as a standard and the carbohydrate content was assessed by the method of Dubois et al.\(^1\) with glucose as standard. The endotoxin content was determined by the chromogenic \textit{Limulus} amoebocyte lysate assay (Pyrogenet, Byk-Mallinckrodt) used according to the manufacturer's instructions. To determine if the osteolytic activity of the SAM was proteinaceous, solutions containing SAM 2\(0\) mg/ml were heated to 80°C for 1 h in a water bath before testing in the bone resorption assay. SAM preparations at a concentration of 2\(0\) mg/ml were also incubated at 4°C for 18 h in the presence of trypsin (Sigma) 0.25%. Soya bean trypsin inhibitor 0.75% was then added before dilution of the SAM and addition to the bone cultures. Controls consisted of cultures of murine calvaria stimulated with SAM incubated at 4°C for 18 h without trypsin and calvaria with the mixture of trypsin and trypsin inhibitor but without the SAM.

\textbf{Electronmicroscopy}

The efficacy of extraction and the subsequent integrity of the bacteria were examined by transmission electronmicroscopy as described previously.\(^2\) Briefly, a part of the bacterial suspension was fixed in glutaraldehyde 3\% in 0.1 M sodium cacodylate buffer for 1 h at room temperature. A second portion was fixed in the same manner except that the fixative also contained ruthenium red, 0.15\% an electron-dense stain, to demonstrate the surface-associated components. Bacteria were then pelleted by centrifugation at low speed, the fixative was decanted and the pellet was washed in cacodylate buffer. Control cells were then post-fixed in osmium tetroxide 1\% in cacodylate buffer for 2 h at room temperature. Test cells were treated identically except that the post-fix also contained ruthenium red 0.15\%. The fixative was decanted after centrifugation, and the pellets were washed in cacodylate buffer, then dehydrated in a graded series of ethanol concentrations and embedded in Araldite. Sections were cut on a Reichert Ultracut E ultramicrotome with a diamond knife and examined (unstained) in a JEOL 100CXII electronmicroscope.

\textbf{SDS-PAGE of SAM}

The proteins present in the saline extracts of the two periodontopathogens were resolved by SDS-PAGE\(^6\) with a commercial Minigel apparatus (SE 250 Hoefer Scientific Instruments, San Francisco, CA, USA).

\textbf{Calvarial bone resorption assay}

Bone resorption was assayed by measuring the release of calcium from 5-day-old mouse calvaria (five per group) with 1.5 ml of BGJ medium (Flow Laboratories, Irvine) supplemented with complement-inactivated rabbit serum (Gibco, Paisley) 5\% and ascorbic acid (Sigma) 50 \(\mu\)g/ml.\(^6\) After 24 h, the culture medium was removed and replaced with fresh medium containing various concentrations of SAM or SAM plus various inhibitors. In all assays, prostaglandin (PG)E\(_2\) was added to five of the wells at 10\(-6\) M as a positive control to show that the bone was responsive. The calvaria were cultured for a further 48 h and then the calcium content of the medium was measured by automated colorimetric analysis.\(^7\) In some experiments, the calvaria were freeze-thawed three times to kill the bone cells.

The statistical significance of the results was determined by use of the two-tailed Student's \(t\) test. A \(p\) value < 0.05 was considered to be statistically significant.

\textbf{Osteoclast isolation and TRAP assay}

Wistar rats (\(<\) 24 h old: Harlan Olac) were killed by cervical dislocation and the long bones were dissected, freed of adherent tissue, minced finely and agitated in a wide-bore pipette. The bone debris was allowed to settle and 100 \(\mu\)l of cell suspension was removed, carefully and added to individual wells in 96-well microtitration plates (Flow Laboratories). The plates were incubated for 30 min, washed three times with Eagles' Minimal Medium (MEM) and SAM from \(A.\) \textit{actinomyctetemcomitans} was added at 10-fold concentrations ranging from 10 ng/ml to 10 \(\mu\)g/ml. The plates were incubated for 24 h at 37°C and tartrate resistant acid phosphatase (TRAP) was measured with a commercial assay kit (Sigma), as a marker of osteoclast activation/differentiation.

\textbf{Osteoclast differentiation assay}

BALB/c mice (6 weeks old: Harlan Olac) were killed by cervical dislocation; the long bones were removed, dissected free of adherent tissue, and split in two. The bone marrow was then removed and washed twice in MEM containing fetal calf serum (FCS) 10\%. The cell suspension was distributed into 24-well culture plates (Flow Laboratories) and incubated for 9 days in the presence of graded concentrations of SAM from \(A.\) \textit{actinomyctetemcomitans} ranging from 1 ng/ml to 10 \(\mu\)g/ml. Fresh medium containing SAM was added every 48 h and, at the end of the incubation period, cells were fixed and cellular TRAP activity was demonstrated by a histochemical enzyme assay (Sigma). TRAP-positive cells containing more than three nuclei were counted as osteoclasts and in each experiment the total number of TRAP-positive cells/well was counted blindly in four wells for each concentration of SAM.

\textbf{Inhibitor studies}

The possible contribution of LPS to the bone resorbing activity of the SAM was determined by
adding polymyxin B (Sigma) 20 μg/ml to the SAM preparations or to A. actinomyctetemcomitans LPS which were both added to calvarial cultures at a concentration of 1 μg/ml. The role of prostanoids in bone resorption was tested by adding the cyclooxygenase inhibitor, indomethacin (Sigma) at 1 μm. The role of interleukin-1 (IL-1) was assessed by adding the IL-1 antagonist protein—IL-1 receptor antagonist (IL-1ra; also known as IRAP Synergy), Boulder, CO, USA)—at concentrations ranging from 100 ng/ml to 10 μg/ml. The involvement of tumour necrosis factor (TNFα) in bone resorption was determined by adding the neutralising monoclonal antibody TN3-19.2 (produced by Professor R. Schreiber, Washington University School of Medicine and manufactured by Celltech Ltd, Slough). Concentrations of antibody added ranged from 0.1 to 10 ng/ml. These inhibitors were added to calvarial cultures at the same time as the SAM, which was used at a concentration of 1 μg/ml in all studies.

Results

Electron microscopy

The ruthenium red-staining extracellular layer that was present on both species was absent after saline extraction and the bacteria were intact with no signs of damage. Also, there was no evidence of fimbriae, pili or S-layers.

Composition of SAM

The protein and carbohydrate content of SAM from A. actinomyctetemcomitans were 44% and 13% w/w, respectively, and for E. corrodens, 16% and 5%. The endotoxin present in 1 mg/ml solutions of SAM from both bacteria was 1–10 ng/mg, and SDS-PAGE analysis revealed proteins with mol. wts ranging from > 70 kDa to c. 14 kDa. The distribution of bands suggested that SAM preparations from these species were different in composition.

Bone resorbing activity of SAM

SAM from both species stimulated reproducibly the release of calcium from cultured murine calvaria and the dose response in one representative assay is shown in fig. 1. The dose range was from 10 ng/ml to 10 μg/ml and the SAM preparations from both A. actinomyctetemcomitans and E. corrodens consistently demonstrated statistically significant activity at the lowest concentration tested (10 ng/ml). In some experiments, both SAMs showed activity at 1 ng/ml.

Additional evidence that the bone resorbing activity of the SAM was not due to LPS contamination was provided when polymyxin B was added to cultures. Polymyxin B binds to and inactivates LPS and this effect can be clearly seen in fig. 2, when it was added to bone cultures exposed to LPS from A. actinomyctetemcomitans. In contrast, the same concentration of polymyxin B had no effect on the bone resorption induced by either SAM preparation. Polymyxin B had no effect by itself when added to bone.

The nature of the bone resorbing activity of SAM was investigated by either heating it to 80°C for 1 h or exposing it to trypsin. Both treatments caused 60% loss in the bone resorbing activity of SAM from both species (results not shown).

Effect of inhibitors

The addition of 1 μm indomethacin to calvarial cultures stimulated with SAM from E. corrodens consistently inhibited calcium release by 20–25%. In contrast, indomethacin did not significantly inhibit bone resorption induced by SAM from A. actinomyctetemcomitans (fig. 3).

The biological actions of IL-1 can be antagonised by IL-1ra and the addition of this natural antagonist protein to unstimulated calvaria had no effect on basal calcium release. In three separate experiments, inhibition of bone resorption by SAM from both organisms was observed only at IL-1ra 10 μg/ml and at this concentration the maximum inhibition of calcium release was only 25% (fig. 4).

TNFα is another potent stimulator of bone resorption and to determine the role of this cytokine in SAM-induced bone resorption, a neutralising antibody to murine TNFα (TN3-19.12) was employed. The addition of this antibody to unstimulated calvaria had no effect on basal calcium release, but in three separate experiments, the addition of TN3-19.12 to calvarial cultures stimulated by SAM from E. corrodens produced almost complete inhibition of bone res-
Fig. 2. The effect of adding polymyxin B (PMB) to calvarial cultures stimulated by lipopolysaccharide (LPS) from *A. actinomycetemcomitans* (Aa-LPS) or by SAM extracted from *A. actinomycetemcomitans* (Aa-SAM) or *E. corrodens* (Ec-SAM). The control culture shows the release of calcium from calvaria in the absence of any stimulus. The positive control (PGE) was stimulated with 1 μM PGE. Each bar represents the mean and SD of five replicate cultures. PMB significantly inhibited calcium release by Aa-LPS (**p < 0.001) but had no effect on that stimulated by the SAM preparations.

Fig. 3. The inhibition of bone resorption induced by SAM from *A. actinomycetemcomitans* (Aa) or *E. corrodens* (Ec) in the absence or presence of 10^{-6} M indomethacin (Indo). The control represents the release of calcium in unstimulated cultures and PGE is the positive control (1 μM PGE). Each bar represents the mean and SD of five cultures. Indomethacin significantly inhibited the bone resorption induced by SAM from *E. corrodens* (*p < 0.05) but did not significantly inhibit bone resorption caused by SAM from *A. actinomycetemcomitans*.

In contrast, the antibody had no effect on the bone resorption induced by SAM from *A. actinomycetemcomitans*.

**Action of SAM from *A. actinomycetemcomitans* on freeze-thawed calvaria**

Calvaria were freeze-thawed to kill the bone cells and exposed to various concentrations of SAM from *A. actinomycetemcomitans* to determine if this material had caused calcium release by a direct proteolytic action. Over 48 h, calcium release was similar when SAM was present or absent in the assay (results not shown).

**Action of SAM from *A. actinomycetemcomitans* on isolated osteoclasts**

Rat osteoclasts were exposed for 24 h to SAM over the dose range 10 ng/ml–10 μg/ml. Even at the highest

**Discussion**

The bone destruction and inflammation characteristic of chronic periodontitis is associated, in an as yet ill-defined manner, with subgingival plaque bacteria and their products. Disease symptoms may be due to the direct action of bacterial products or they may result from the stimulation of host mechanisms by these bacterial products. In the context of bone destruction, bacterial substances may activate osteoblasts or osteoclasts directly or they activate these cells indirectly by stimulating the synthesis of osteolytic mediators such as prostanoids or cytokines. The latter may require other cell populations (bone fibroblasts, leucocytes, etc.) to synthesise these mediators (i.e., paracrine stimulation) or it may work via an autocrine route in which the cell responding to these osteolytic mediators is also the cell synthesising the mediators. However, a prerequisite for bone destruction is that the bacterial components actually reach the target cells. In this respect, biologically active soluble surface components, especially those that could be shed during the growth of the organism, surface-associated proteins capsular material, S-layers, slime and fibrils, clearly have a greater "bio-availability" than less soluble components that are an integral part of the cell, e.g., LPS. The latter forms an integral part of the outer membrane of the gram-negative cell wall although it may be shed during growth and has low solubility in a physiological milieu.

Saline extraction and acetone precipitation allowed the recovery of a complex mixture of proteins and carbohydrates but left the bacteria intact. The
majority of the material isolated was protein with a protein to carbohydrate ratio of between 2:1 and 3:1. SDS-PAGE analysis revealed a mixture of proteins in the mol. wt range of c. 14–70 kDa and a different pattern of bands for each SAM.

In a previous study, SAM from A. actinomyetemcomitans proved to be a more potent stimulator of bone resorption than LPS. In comparison, the osteolytic activity of SAM from Porphyromonas gingivalis was far less potent, and was completely blocked by indomethacin, IL-1ra or anti-TNFα. The results of this study demonstrated that SAM from E. corrodens also stimulates calvarial bone resorption and, on a dry weight basis, is as potent as that from A. actinomyetemcomitans. The nature of the active components is being investigated but since bone resorbing activity of the SAM from these three species is inhibited significantly by both heating or trypsin treatment, it is likely that protein is involved.

These findings demonstrate that the osteolytic activity of the SAM from A. actinomyetemcomitans is not a property unique to this organism but may be shared by a range of gram-negative periodontopathetic bacteria. This strengthens the hypothesis that the readily solubilised surface constituents of bacteria within the periodontal pocket play a role in a alveolar bone destruction in patients with periodontal disease.

The Limulus assay demonstrated that the endotoxin contamination of the extracted SAM was between 1–10 ng/mg. Even at the highest concentration of SAM used in these assays (10 μg/ml) this represents only 10 pg of LPS/ml in the calvarial media at which concentration, based on our previous studies the LPS is unlikely to have any effect. However, to rule out the possibility that the effects seen may be due to synergy between SAM and LPS polymyxin B, a cationic peptide which inactivates LPS, was added to cultures. The bone resorbing activity of LPS from A. actinomyetemcomitans was completely inhibited but the activity of the two SAM preparations was unaffected, strongly suggesting that the osteolytic activity was not due to contamination with LPS. This was further supported by the heat lability of the bone-resorbing components of the SAM preparations.

Bone resorption can be induced or stimulated by a number of pro-inflammatory mediators and, in the context of periodontal disease, perhaps the most inflammatory cytokines IL-1 and TNFα. To determine the role played by prostanooids in SAM-induced bone destruction, indomethacin was added at a concentration that should completely block cyclooxygenase activity without producing the serious nonspecific effects that can be found with higher concentrations of this drug. Previously the addition of indomethacin has been shown to inhibit almost completely the bone resorption induced by LPS from A. actinomyetemcomitans at 1 μM and SAM from P. gingivalis. In contrast, indomethacin had little effect on the bone resorption induced by the SAM from A. actinomyetemcomitans and had only a moderate effect (20–25% inhibition) on the activity of SAM from E. corrodens.

IL-1 is probably the most potent activator of bone resorption, at least in vitro and, recently, a natural antagonist, IL-1ra, has been cloned and expressed. This protein binds to the type I IL-1 receptor without triggering an agonist response and thus acts as a true receptor antagonist, blocking the biological activity of IL-1 both in vitro and in vivo. IL-1ra can inhibit calvarial and long-bone resorption induced by human recombinant IL-1 in vitro. IL-1ra had only a minimal effect on bone resorption induced by SAM from the two species tested here and only at high concentrations (10 μg/ml) which contrasts with its ability to inhibit the bone resorption induced by the SAM from P. gingivalis (100 ng/ml).

TNFα is also capable of stimulating bone resorption and if it was produced by the calvaria in response to SAM then the MAb TN3-19, which neutralises the biological activity of TNFα, should inhibit bone resorption. At a concentration of 1 μg/ml, this MAb inhibited the activity of SAM from E. corrodens by almost 80%, which is similar to the result for SAM from P. gingivalis. In contrast, the activity of SAM from A. actinomyetemcomitans was not affected by neutralisation of TNFα.

The mechanisms by which the three SAM preparations stimulate bone resorption are clearly very different. The osteolytic activity of SAM from P. gingivalis could be inhibited completely by blocking prostanooid synthesis or by neutralising the actions of IL-1 or TNFα. The bone resorbing activity of the SAM from E. corrodens was slightly inhibited by indomethacin and almost completely inhibited by neutralising TNFα. In contrast, the osteolytic effect of SAM from A. actinomyetemcomitans was unaffected by these various inhibitors. This suggests that the SAM from P. gingivalis caused bone resorption by stimulating bone cells to synthesise IL-1 and TNFα, which then caused the synthesis of prostanooids. These various mediators presumably act synergically, which is why removal of any one of them inhibits bone resorption. The SAM from E. corrodens would appear to promote bone resorption largely by stimulating the synthesis of TNFα, with the production of osteolytic prostanooids playing a minor role.

The mode of action of the SAM from A. actinomyetemcomitans is uncertain but does not appear to involve established osteolytic mediators. The activity of SAM from A. actinomyetemcomitans is not due to the presence of neutral endopeptidases capable of cleaving the conventional proteinase substrates—casein and gelatin (unpublished observations)—and it failed to release calcium from freeze-thawed calvaria where the bone cells have been killed, thus ruling out a direct effect on the matrix of the calvarial bone. Bone resorption is a complex event involving two main cell populations—osteoblasts and the osteoclasts—with the possible participation of other cells such as...
periosteal fibroblasts and osteocytes. Our initial assumption was that bacterial SAM stimulated cells in the calvaria to generate osteolytic signals (prostanoids and cytokines) which eventually led to the activation of the bone-resorbing osteoclasts. The finding that the SAM from \textit{Actinomyces viscosus} was unaffected by any of the inhibitors and had no obvious proteolytic action suggested that it might directly influence osteoclasts. The possibility was addressed by adding SAM to cultured rat long bone osteoclast cultures. No evidence was found for the activation of the osteoclast enzyme, tartrate-resistant acid phosphatase (TRAP; a marker of osteoclast activation) suggesting that this material is not capable of directly interacting with osteoclasts to produce bone destruction. However, in the murine bone marrow assay, which is used commonly to test agents capable of stimulating the differentiation of osteoclast precursor cells, SAM from \textit{A. actinomyces viscosus} did stimulate TRAP-positive multinucleate cell formation, but the dose response was shifted to the right by one log dose compared to that in the murine calvarial bone resorption assay. Thus, it is still not established what osteolytic signals are stimulated by the SAM from \textit{A. actinomyces viscosus} and it is possible that it stimulates both osteoblasts and osteoclasts to promote bone resorption. Previously we have reported that the SAM from this organism possesses IL-1-like activities\textsuperscript{23} and we are currently fractionating the proteins present in this SAM to isolate this cytokine-like factor.

We thank the Wellcome Trust for financial support S.M. We also thank R. Thompson of Synergen for the gift of IL-1ra; R. Schreiber, Washington University School of Medicine, St Louis, who produced the hamster antibody TN3-19; and Dr M. Bodmer, Celltech, who supplied the bulk-cultured antibody.
