MOLECULAR DIAGNOSIS

PCR identification of *Pseudomonas aeruginosa* and direct detection in clinical samples from cystic fibrosis patients

This report describes a PCR primer pair that targets the *algD* GDP mannose gene of *Pseudomonas aeruginosa* and produces a specific 520-bp PCR product useful for *P. aeruginosa* identification. This PCR assay was tested with 182 isolates of *P. aeruginosa* and 20 isolates of other bacterial species, and demonstrated 100% specificity and sensitivity. The test was also able to detect *P. aeruginosa* directly in clinical samples such as sputum or throat swabs obtained from cystic fibrosis patients. The combination of this primer with a universal bacterial primer, acting as a control to assess DNA quality in the sample, resulted in a robust PCR method that can be used for rapid *P. aeruginosa* detection.

Introduction

*Pseudomonas aeruginosa* is a common cause of nosocomial infection and the most important pathogen for cystic fibrosis (CF) patients. It plays an important role in the pathogenesis of CF pulmonary disease, and once established in the airways of these patients is seldom eradicated [1, 2]. Initial intermittent colonisation of the upper respiratory tract usually precedes chronic endobronchial colonisation with mucoid strains and this in turn is associated with progressive deterioration of lung function [3], the leading cause of death among these patients [1, 4].

Alginate production plays a central role in the pathogenesis of chronic pulmonary infection in CF patients, and almost all patients colonised with *P. aeruginosa* will acquire mucoid (alginate-producing) strains [4–6]. Alginate synthesis is regulated by several genes, but the *algD* gene – which codes for GDP mannose dehydrogenase – seems to occupy a strategic position in the regulation of alginate synthesis, as this enzyme is the first enzyme specific for alginate production in the alginate biosynthetic pathway [6, 7].

Once diagnosed, all patients with CF are periodically assessed for airway colonisation, and some CF centres recommend aggressive treatment after the first isolation of *P. aeruginosa* in an attempt to eradicate it [8, 9]. Microbiological identification of the bacteria is usually easy to perform, but negative culture results can occur during antibiotic treatment or in patients with a small number of bacteria in the airways. Furthermore, the assessment of airway colonisation in children younger than 5 years old is less reliable, as they usually cannot produce sufficient amounts of sputum for microbiological analysis, and throat swabs must be collected instead.

This report describes a new specific primer pair targeting the *algD* gene of *P. aeruginosa*, suitable for identification of the organism by PCR. This primer pair was also used along with a universal primer pair for bacteria [10], to assure DNA quality in samples negative for *P. aeruginosa*.

Materials and methods

Bacterial strains

A total of 182 *P. aeruginosa* strains from different sources and geographic regions was employed in this study (Table 1); 20 strains of other bacterial species of medical importance which colonise CF patients were studied: *Staphylococcus aureus, Streptococcus pneumo-

*Samples from CF patients.
1Clinical samples, non-CF patients.
2Miscellaneous samples: tracheal aspirate, bronchoalveolar lavage fluid, surgical wound, urine, ocular secretion, venous catheter.

*C. maltophilia, Haemophilus influenzae, Escherichia coli, Klebsiella pneumoniae, Acinetobacter calcoaceticus, Enterobacter aerogenes, P. stutzeri, Stenotrophomonas maltophilia and Burkholderia cepacia.*

Cultures and DNA extraction

The bacteria were cultivated on a selective medium (Bacto Cetrimide Agar Base, Difco), identified by standard microbiological methods, and, when necessary, by complementary biochemical tests. Throat samples were first incubated in liquid thioglycolate medium (Difco) at 37°C for 24 h. Bacteria were collected directly from the culture plate, washed twice in a solution of 10 mM Tris HCl and 1 mM EDTA, pH 8.0 (TE) and incubated in 50 mM Tris, pH 8.0, containing SDS 0.5% and proteinase K (Gibco-BRL) 200 μg/ml for 2 h at 65°C. This was followed by two organic extractions with phenol and one with chloroform [11]. DNA was precipitated with cold ethanol, centrifuged, dried and resuspended in TE buffer, pH 8.0. The DNA concentration was then assessed at 260 nm in a spectrophotometer (Pharmacia, São Paulo, Brazil).

Direct detection in clinical samples

Direct detection of *P. aeruginosa* by PCR was tested on 15 clinical samples (sputum and throat swabs) from CF patients who attended the Pediatric Pulmonology Outpatient Clinic of Instituto da Criança, São Paulo. All the sputum specimens were divided into two portions and one of them was cultivated as described previously. Throat samples were collected by one of us (L.V.F.S.F.) using two swabs simultaneously, one was cultivated and the other was used for the PCR assay. Written informed consent was obtained from the parents for the collection of each specimen, in accordance with the ethical guidelines of the Institution.

DNA extraction

Clinical samples were processed as described by Campbell *et al.* [12]. Sputum samples were diluted in an equal volume of 100 mM Tris, 90 mM boric acid and 1 mM EDTA, pH 8.0 (TBE). Throat swabs were soaked in 1 ml of the same solution and shaken vigorously. The diluted samples were then frozen instantaneously in liquid nitrogen, boiled for 30 min and centrifuged at 13,800 *g* for 5 min. The supernatant fraction was separated and 5 μl were used directly for the PCR reactions.

Sensitivity assay

Serial dilutions from 20 ng/μl to 2 fg/μl of *P. aeruginosa* DNA, obtained from cultures, were added to a clinical sample from a throat swab without *P. aeruginosa*, to estimate the sensitivity of the method for direct detection.

Primer selection

The *algD* GDP mannose dehydrogenase gene of *P. aeruginosa* contains 2032 bp (GenBank, access no. 400337, identification no. g45267) and its expression results in a 48-kDa protein, the enzyme GDP mannose dehydrogenase, the first enzyme that is specific for alginate production in the alginate biosynthetic pathway [7]. The promoter region of this gene is well known for its regulatory role in the transcription of other genes involved in alginate biosynthesis [6]. The selected primers VIC1 (5'TTCCCTCAGGAGAAACATCT 3') and VIC2 (5'CTGCTTTGATCAGGTCGATCT 3') were designed to amplify a 520-bp segment of the *algD* GDP mannose dehydrogenase gene of *P. aeruginosa*. Bacterial universal bacterial primers 11E-13B, targeting the 16 S RNA gene of bacteria [10] were also employed, to assure DNA quality.

PCR conditions

PCR was performed in a 25-μl reaction mixture containing 150 ng of DNA template or 5 μl of the processed clinical samples, 0.4 μmol/L of each primer, 200 μmol/L each of the four nucleotide triphosphates, 2 mM MgCl₂, 50 mM KCl, 10 mM Tris (pH 8.0) and 1 U of Taq DNA polymerase (Pharmacia). Samples were subjected to the following thermocycling process (Perkin Elmer 2400): 94°C for 5 min, followed by 30 cycles of 94°C for 1 min, 60°C for 1 min and 72°C for 1 min. A final extension step at 72°C was continued for another 7 min. A tube containing the reaction mixture and sterile water was included in all reactions as a negative control.
Results

Bacterial isolates

A total of 182 P. aeruginosa isolates from multiple sources was tested in the PCR protocol and a positive identification, characterised by the presence of a specific 520-bp product, was obtained with 176 samples. The six samples that did not show the specific 520-bp product were isolated from CF patients at the Instituto da Criança, São Paulo, Brazil. These isolates were re-submitted for microbiological identification and were found to be B. pickettii (two isolates), P. mendocina (two), Alcaligenes xylosoxidans (one) and P. putida (one) (Fig. 1). As a control, concomitant re-identification of 12 P. aeruginosa PCR-positive isolates resulted in confirmation of the bacterial identity of all specimens.

The specificity of PCR with the primer pair VIC1-VIC2 was tested against a panel of strains of bacterial species which are of medical importance and known to colonise CF patients (Fig. 2). A 233-bp fragment, which is the expected result of amplification with the bacterial universal primers, confirmed successful DNA extraction, while a specific fragment of 520 bp was seen only in the samples of P. aeruginosa DNA. The sensitivity of the method was also tested with P. aeruginosa DNA amounts ranging from 100 ng to 100 fg (results not shown). Adequate products were obtained with a minimum of 100 pg of P. aeruginosa DNA, which corresponds to c. 8 x 10^3 bacteria [13].

Clinical samples

A total of 15 clinical samples was collected and tested by the PCR method, with concomitant culture as described above (Table 2). Positive PCR identification of P. aeruginosa was obtained in seven samples, all but one positive by culture (Fig. 3). One sample positive by culture for P. aeruginosa gave a negative PCR test; this sample did not show the 233-bp product, corresponding to the amplification of bacterial ribosomal DNA. With this exception, all the other 14 samples tested produced the amplification product for bacterial ribosomal DNA. One of the P. aeruginosa culture-negative samples yielded a 520-bp product in the PCR reaction. This sample was collected from a CF patient with chronic colonisation by P. aeruginosa whose subsequent culture (2 weeks later) grew P. aeruginosa. Other microorganisms identified in cultures were Staph. epidermidis, E. coli, Pseudomonas sp., Staph. aureus, H. influenzae, Aspergillus sp. and Candida sp.

Frequently, sputum samples produced smears on the agarose gel that were attributed to an excess of DNA. In these instances, the samples were diluted in sterile water and repeat of the PCR resulted in proper amplification and product visualisation.

Discussion

The sequence of the algD GDP mannose gene described by Deretic et al. [7] was chosen as the target for the PCR protocol because of its importance to the P. aeruginosa species. It codes for a pivotal enzyme of the alginate biosynthetic pathway and this polymer represents an important protective mechanism for the bacteria. McIntosh et al. [14] have described a PCR protocol focused on this gene, targeting a locus c. 500 bp distant from the promoter region. They demonstrated its specificity as a target for PCR identification of P. aeruginosa in a study of a small but representa-

Fig. 3. Agarose gel electrophoresis of PCR products from clinical samples. Lanes: M, mol. wt marker (100-bp ladder); 1, *P. aeruginosa* strain from São Paulo, Brazil; 2, *S. maltophilia* strain; 3–12, sputum samples; 13–17, throat swab samples; 18, negative control (no DNA added); 1, *P. aeruginosa*, positive control; 4, 5, 8, 9, 12, 15, 17, *P. aeruginosa*-positive samples; 10, represents a sputum sample that did not result in PCR products (see Table 2).

O’Callaghan et al. [15] also described a PCR assay for *P. aeruginosa* and *B. cepacia* identification which used 16S RNA sequence amplification followed by hybridisation with specific oligonucleotide probes. This method proved to be highly reproducible and sensitive, and was also applied to direct detection in sputum samples. Campbell et al. [12] have also focused on specific 16S RNA PCR for *B. cepacia* identification. In a recent publication, De Vos and co-workers [16] described a multiplex-PCR protocol targeting the outer-membrane lipoprotein genes *oprI* and *oprL*, which was able to identify *P. aeruginosa* and other fluorescent *Pseudomonas* strains, and was also suitable for direct detection in sputum and skin biopsy samples.

In the present study, a similar approach of developing a PCR methodology for *P. aeruginosa* identification was used, with the *algD* GDP mannose dehydrogenase gene as the target. A large number of strains from different sources and geographical locations was tested and a sensitive and specific method for *P. aeruginosa* identification was obtained. The direct detection of *P. aeruginosa* in clinical samples was also attempted, including samples from throat swabs, as this is the source of material commonly used to assess bacterial colonisation in young CF patients. The method used for sample processing [12] was chosen because of its simplicity, but further studies on the use of substances such as phenol or guanidine thiocyanate in the DNA extraction step may provide higher sensitivity, because this may eliminate inhibitory agents present in some clinical samples.
The assay has been standardised and can be used directly on clinical samples, with the advantage of the concurrent use of a set of universal bacterial primers to assure DNA quality in P. aeruginosa PCR-negative samples. The study of respiratory samples allowed the use of this kind of control, as these samples will always contain some bacterial DNA from the normal flora. Interestingly, some of the patients submitted to sample collection (B, C, D and H) were on aerosolised dornase alpha (Pulmozyme<sup>®</sup>) therapy [17], but this apparently did not influence the results, except for one sample (H) that did not yield any PCR product.

Further studies with a large number of clinical samples and quantitative bacterial cultures are necessary to determine the real usefulness of this method in the clinical management of these patients. The possibility of simultaneous detection of other bacteria such as Staph. aureus and B. cepacia is another aspect to be studied further, and would represent a major advance in CF patient care. In conclusion, a simple, specific and sensitive method has been developed for identification of P. aeruginosa that can be applied directly to clinical samples, and its execution requires <6 h from sample preparation to final result.

We thank Dr Otavia Luisa Silva Damas de Caballero (Ludwig Institute for Cancer Research, São Paulo branch) for helpful advice, and Dr David P Speert and his team for providing bacterial samples and constant support. We also thank Dr Claudio Sérgio Pannuti and colleagues at the Laboratory of Virology (Instituto de Medicina Tropical de São Paulo) for technical assistance and for encouraging and supporting this work. This study was supported by Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP), grant no. 1995/00033-6. L.V.F.S.F. is sponsored by CAPES, Brazil.
