Mostly Pneumocystis carinii isolates from patients with acute pneumocystosis (PCP) have been typed until now. This report describes the typing of P. carinii organisms obtained from an HIV-negative patient without PCP. The patient underwent a broncho-alveolar lavage (BAL) to investigate an abnormal chest X-ray. He was diagnosed with sarcoidosis. However, a low level of P. carinii organisms undetectable by microscopy was detected in BAL fluid by two subsequent nested PCR assays: one assay amplifying a portion of the mitochondrial large subunit RNA gene and a second one amplifying the internal transcribed spacers (ITS) 1 and ITS 2 of the nuclear rRNA operon. This low level of the fungus did not reflect acute PCP. Indeed, the clinical outcome was improvement despite the absence of specific treatment. The patient was considered to be only colonised by the fungus. Analysis of sequences of ITS PCR products led to identification of genotype Gg. This information constitutes the first data concerning P. carinii ITS genotype from a patient without acute PCP and HIV. This type has been described previously in AIDS patients diagnosed with PCP. These results show that PCR and ITS genotyping could represent efficient tools for the further investigation of the role played by HIV-negative patients with pulmonary colonisation in the human reservoir of P. carinii.

Introduction

Pneumocystis carinii remains the most frequent opportunistic micro-organism causing severe pneumonia in immunosuppressed patients. Over the last decade, pulmonary carriage of P. carinii in healthy persons has been re-evaluated and P. carinii pneumonia (PCP) is now frequently considered to result from de novo infection rather than from reactivation of latent infection [1].

Nevertheless, low numbers of P. carinii organisms, undetectable by microscopy, have been detected by PCR assay on broncho-alveolar lavage (BAL) fluids from patients with no evidence of acute PCP. These low fungus levels were considered to reflect pulmonary colonisation. These cases of colonisation with P. carinii have been described mainly in patients with immunodeficiency and in those with pulmonary diseases [2–4].

As PCR is not usually used for the routine detection of P. carinii in pulmonary samples, diagnoses of cases of pulmonary colonisation with P. carinii are frequently missed. For this reason, and because the fungus is not easily cultivable, P. carinii strains responsible for colonisation have been typed in only one instance [5].

The aim of the present study was to describe the type of P. carinii obtained from an immunosuppressed HIV-negative patient with pulmonary colonisation. P. carinii was detected by PCR in a BAL fluid sample and was typed by PCR product sequencing. The genotype obtained from this patient without PCP was compared with genotypes described in recent reports concerning patients with acute PCP [6–8].

Patient and methods

Pulmonary colonisation was diagnosed in a 45-year-old patient who was submitted to BAL procedure to investigate pulmonary interstitial syndrome. The patient had no past history of PCP or HIV infection. Underlying conditions were diabetes and panhypoipituitarism.
treated with hydrocortisone. The blood CD4+ T-cell count and the CD4+ T cell/CD8+ T cell ratio were 389 × 10^6/L and 0.46, respectively.

P. carinii was not detected on BAL fluid sediment by methanol-Giemsa stain and an indirect immunofluorescence assay (IFA) with an anti-P. carinii cyst monoclonal antibody (Monofluo Kit® P. carinii, Diagnostics Pasteur, Marnes-La-Coquette, France). P. carinii DNA was detected by a hemi-nested PCR assay with a rapid DNA extraction procedure (GeneReleaser®, BioVentures, Murfreesboro, TN, USA) and specific primers pAZ102-H and pAZ102-E (first PCR round), and pAZ102-L2 and pAZ102-E (second PCR round) amplifying a portion of the gene encoding the mitochondrial large subunit RNA [9–10]. These PCR results were not used in patient management; however, the patient was followed-up for 12 months after the BAL procedure. As he did not develop PCP despite the absence of specific treatment for P. carinii, he was considered to be only colonised by P. carinii. Pulmonary sarcoidosis was finally diagnosed. Clinical improvement was obtained after corticosteroid treatment.

The fungus was typed by sequence analysis of the internal transcribed spacers (ITS1 and ITS2) of the nuclear rRNA operon. ITS types are defined by a combination of the alleles of the two loci ITS1 and ITS2. After a classical extraction procedure on the remaining BAL fluid sediment with proteinase K and phenol-chloroform, a second nested PCR was performed with the two pairs of primers NITSF and NITSR (first PCR round), and ITS5F and ITS2R3 (second PCR round) [6,7]. The products of the second PCR round were cloned (pGEM-T vector System II, Promega Corporation, Madison, WI, USA) and sequenced from the two strands (Sequenase, Version 2.0, DNA sequencing kit, US Biochemical, Cleveland, OH, USA). The sequences were compared with those reported by Tsolaki et al. [6,7] and Lee et al. [8].

**Results**

Considering sequence references and scores described for typing by Tsolaki et al. [6,7]: an ITS1 allele similar to allele A2 and A3 that was designated ‘A’, was found in the BAL fluid sample. However, it differed by T residues at positions 2 and 16. This allele ‘A’ was associated with ITS 2 allele a3. Thus, P. carinii genotype ‘Aa3’ was identified (Table 1). According to sequence references and applying the score of Lee et al. [8], genotype ‘Aa3’ was similar to genotype Gg.

**Discussion**

The possibility that the positive result of PCR detection could be related to sample contamination by fibroscopes previously used for patients with PCP was improbable. No case of acute PCP was noted during the same period. Moreover, as several negative controls were used (distilled water), contamination of samples by the airborne route in the laboratory, before and within PCR processing, was also excluded. Furthermore, P. carinii was detected by two nested PCR assays which were performed after two different extraction procedures and with specific primers from two different loci. These data were consistent with a genuine presence of the fungus in the respiratory tract of the patient. Nevertheless, for ethical reasons, no subsequent BAL was performed to confirm this presence.

Although this patient was not infected by HIV, he presented with an underlying pulmonary disease associated with an impairment of cellular immunity; the CD4+ T-cell count and the CD4+ T cell/CD8+ T cell ratio were 389 × 10^6/L and 0.46, respectively (N >600 and >1). It has been shown that an increasing risk of pulmonary colonisation with P. carinii in patients without HIV is associated with both a CD4+ T cell count < 400 × 10^6/L and a CD4+ T cell/CD8+ T-cell ratio <1 [4]. Thus, detection of P. carinii in this patient was consistent with his immune status.

Genotype Gg was identified in an immunosuppressed HIV-negative patient with colonisation. These are the first data concerning P. carinii ITS genotype from a patient without acute PCP. Genotype Gg was previously observed by Lee et al. [8] in Danish and American patients. All of these patients developed PCP and most of them were HIV-infected. This genotype was rarely observed in patients from the USA and Europe (5% of

*ITS genotype of P. carinii defined by combination of the alleles of the loci ITS 1 and ITS 2. Scores in references 6 and 7 were used for typing.

*Allele ‘A’ differed from alleles A2 and A3 previously reported in references 6 and 7, by T residues at positions 2 and 16. Alleles A2 and A3 differed from ‘A’ by a C residue at position 2 and an A residue at position 16 respectively. Alleles ‘A’ and a3 were similar to alleles G and g described in reference 8.

typed isolates), whereas the most frequent genotype was type Eg (20% of typed isolates) [8].

Genotype Gg was also found in one BAL fluid sample from a patient with PCP and AIDS, who was admitted to this hospital 5 weeks after the patient with sarcoidosis (data not shown). At present these results indicate that a similar P. carinii genotype could be found in an immunosuppressed HIV-negative patient with pulmonary colonisation and in patients with acute PCP and HIV. These results are consistent with those previously obtained using another typing method [5].

Host-to-host transmission of the micro-organism has been proved in rodents [11] and several observations suggested that inter-individual transmission occurred in man. Moreover, the host specificity of the fungus also pleads in favour of PCP as an anthropoposis. The above data are consistent with a human reservoir for P. carinii f. sp. hominis (human-derived P. carinii).

A recent study showed that the prevalence of pulmonary colonisation with P. carinii f. sp. hominis in patients with underlying pulmonary diseases and without HIV was 14% [4]. The hypothesis that this patient population could play a role as a reservoir of P. carinii f. sp. hominis cannot be ruled out and must be investigated. Although only one isolate was typed in the present study, results have shown that ITS genotyping of isolates from colonised patients could represent an efficient tool for further investigations concerning this hypothesis.
