The object of this study was to develop and characterize experimental *Burkholderia mallei* aerosol infection in BALB/c mice. Sixty-five mice were infected with 5000 [approx. 2.5 median lethal doses (MLD)] *B. mallei* strain ATCC 23344¹ bacteria by the aerosol route. Bacterial counts within lung, liver, spleen, brain, kidney and blood over 14 days were determined and histopathological and immunocytochemical profiles were assessed. Mortality due to *B. mallei* infection occurred between days 4 and 10 post-infection. Bacterial numbers were consistently higher in the lungs than in other tissues, reaching a maximum of approximately $1.0 \times 10^6$ c.f.u. ml⁻¹ at 5 days post-infection. Bacterial counts in liver and spleen tissue remained approximately equal, reaching a maximum of approximately $1.0 \times 10^3$ c.f.u. ml⁻¹ at day 4 post-infection. By day 14 post-infection, bacterial counts were in the range $1.0 \times 10^3 – 1.0 \times 10^4$ c.f.u. ml⁻¹ for all tissues. Infection of the lungs by *B. mallei* resulted in foci of acute inflammation and necrosis. As infection progressed, the inflammatory process became subacute or chronic; this was associated with the development of extensive consolidation. Lesions in liver and spleen tissue were typical of those that might be expected in bacteriaemia or bacterial toxemia. These results suggest that the BALB/c mouse is susceptible to *B. mallei* when delivered by the aerosol route and that this represents a model system of acute human glanders that is suitable for research into the pathogenesis of and vaccines against this disease.

INTRODUCTION

*Burkholderia mallei*, the causative agent of glanders, is a Gram-negative, aerobic bacillus. Glanders, primarily a disease of horses that is rarely seen in man, is generally confined to equines in parts of the Middle East, Asia and South America. In humans, it is primarily an occupational disease that affects individuals who have close contact with infected animals, such as veterinarians, grooms and farmers (Sanford, 1995). Infection results primarily from contamination of wounds, abrasions or mucous membranes; a number of laboratory-acquired cases of glanders have been reported (Howe & Miller, 1947; Srinivasan et al., 2001).

Human *B. mallei* infection can present as either nasal–pulmonary (glanders) or cutaneous (farcy) infection and the disease may be acute or chronic (Howe et al., 1971). Acute *B. mallei* infection in humans is characterized by rapid onset of pneumonia, bacteriaemia and pustules, leading to death within 7–10 days unless appropriate antibiotic treatment is initiated (Howe, 1949). Various animal models of human *B. mallei* infection have been reported previously, including monkeys (Manzeniuk et al., 1996, 1997; Khomiakov et al., 1998), guinea pigs (Miller et al., 1948), hamsters (Miller et al., 1948; Diadishchev et al., 1997; Fritz et al., 1999; Russell et al., 2000) and mice (Miller et al., 1948; Alekseev et al., 1994; Manzeniuk et al., 1999; Fritz et al., 2000; Amemiya et al., 2002).

Previous workers have reported the development of an intraperitoneal model of *B. mallei* infection in the BALB/c mouse (Fritz et al., 2000) and hamster (Fritz et al., 1999). The hamster proved to be highly susceptible to *B. mallei* infection and all tissues were ultimately affected. In contrast, the BALB/c mouse was less susceptible and infection was limited predominantly to reticuloendothelial tissues, such as spleen, liver, lymph node and bone marrow. Pulmonary involvement was reported as minimal. Acute glanders in humans is often characterized by rapid onset of pneumonia (Minett, 1930); therefore, the aim of this study was to develop a relevant model of human glanders in the mouse by delivery of bacteria in small-particle aerosols. This model could then be used to investigate the pathogenesis of *B. mallei* and aid in the development of relevant antimicrobial and vaccine studies.
METHODS

Bacteria. *B. mallei* strain ATCC 23344\(^T\) was obtained from the American Type Culture Collection and was recovered originally from a case of human glanders in China. Stocks of *B. mallei* were prepared by inoculation of a single colony of each organism grown for 48 h on nutrient agar plates (bioMérieux) into 100 ml nutrient agar broth. Broths were incubated at 37 °C on a rotary shaker (175 r.p.m.) for 48 h. Aliquots (0.5 ml) of broth were frozen at −80 °C by using PROTECT beads (TSC) according to the manufacturer’s instructions. *B. mallei* was cultured by adding five PROTECT beads to 100 ml nutrient broth and incubating on a rotary shaker (175 r.p.m.) for 48 h at 37 °C.

Infection of animals. All animal studies were carried out in accordance with the Scientific Procedures Act (Animals) 1986 and the Codes of Practice for the Housing and Care of Animals Used in Scientific Procedures, 1989.

A Collison nebulizer that contained 20 ml *B. mallei* at a concentration of 2.64 \(\times 10^8\) c.f.u. ml\(^{-1}\) (undiluted 2-day broth suspension) and three drops of Antifoam 289 (Sigma) was used to generate aerosol particles. Particle size of aerosol produced in this manner is approximately 1–3 \(\mu\)m. Control experiments showed that Antifoam was not detrimental to either the bacterial culture or the animals. The aerosol was conditioned in a modified Henderson apparatus (Druect, 1969). Fifty-six barrier-reared, female, 6–8-week-old BALB/c mice (Charles River Laboratories) were placed in a nose-only exposure chamber and exposed for 10 min to a dynamic aerosol. The aerosol stream was maintained at 50–70% relative humidity and 22 ± 3 °C. Fifty-five mice were kept for histological and bacteriological time-point studies and a separate group of ten animals was retained for mortality studies.

Challenged mice were removed from the exposure chamber and returned to their home cages within an ACDP (Advisory Committee on Dangerous Pathogens) animal containment level 3 facility. Animals were observed closely over a 14-day period for development of symptoms and, where appropriate, time to death was carefully recorded. Malaise was noted in some animals, as were immobility and ruffled coat. Humane end points were strictly observed so that no animal became distressed. ‘Time to death’ figures included those animals culled according to the humane end point.

Enumeration of viable bacteria in organs. At various time-points after infection, the number of viable bacteria present in blood and various organs was determined. Organs were removed aseptically and homogenized in 2 ml nutrient broth in a tissue homogenizer (Medicon). Bacteria were enumerated after plating of 0.25 ml tissue homogenate (1:10 serial dilutions in nutrient broth) onto nutrient agar in duplicate and incubating for 48 h at 37 °C. For enumeration of bacteria in blood, an undiluted 0.1 ml sample was plated out in duplicate and the number of viable bacteria was determined as described above. Counts were expressed as c.f.u. (ml homogenized tissue or blood)\(^{-1}\).

Median lethal dose (MLD) determination. Groups of five mice were infected by the aerosol route with appropriate dilutions of *B. mallei* as described above and deaths were recorded over 4 weeks. MLD by the intraperitoneal route, was non-lethal to BALB/c mice at doses up to and including 10\(^6\) bacteria for up to 35 days post-infection (M. S. Lever, unpublished observation); however, an intraperitoneal LD50 of 7 \(\times 10^5\), using the same strain of *B. mallei* in BALB/c mice, has been reported previously (Fritz et al., 2000). It has been shown that the virulence of *B. mallei* can be increased by successive animal passage (Minett, 1930); however, the strain used in this study had not undergone any such passage. This may explain the discrepancy of MLD data in the present study compared to those of other groups. Increased lethality achieved with aerosol compared to intraperitoneal challenge has also been observed with the closely related bacterial species *B. pseudomallei* (M.S. Lever, unpublished observation; Jeddeloh et al., 2003). A possible cause for this route-dependent susceptibility may be the large lung epithelial surface area, with associated macrophages and plentiful blood supply. This would result in efficient uptake of bacteria by macrophages and neutrophils and the subsequent dissemination of bacteria throughout the body. In contrast, a smaller cellular surface area with a more limited blood supply, such as that in the peritoneal cavity, could result in less efficient uptake and transport of bacteria to local lymph nodes.

Histopathological studies. Starting from 24 h post-infection, the lung, liver, spleen, kidney and brain were taken for histology from one animal per time-point. Tissues were fixed in 10% formaldehyde solution, processed for paraffin wax embedding by using standard techniques and sections (5 \(\mu\)m) were cut and stained with haematoxylin and eosin (H&E).

Immunohistochemical studies. Immunohistochemical procedures were performed on sections (5 \(\mu\)m) cut from paraffin-embedded tissues, mounted on Snowcoat X-tra slides (Surgipath), dewaxed in xylene and rehydrated through decreasing concentrations of industrial methylated spirit (99%) to distilled water. Immunohistochemical staining was performed by using the Dako ARK (Animal Research Kit) immunohistochemical staining kit according to the manufacturer’s instructions with the following modifications: enzyme predigestion with proteinase K for 5 min and protein block (serum-free) for 5 min. This kit was designed to eliminate endogenous immunoglobulin background staining. The primary antibody was a murine mAb (3V1E5) that was specific for exopolysaccharide antigen from *B. mallei* and *Burkholderia pseudomallei*. A murine mAb specific for *Mycobacterium tuberculosis*, used as primary antibody, and sections of non-infected mouse lung, liver and spleen served as negative controls. Positive control material was taken from BALB/c mice 14 days post-aerosol infection with *B. mallei*.

RESULTS AND DISCUSSION

MLD for *B. mallei* ATCC 23344\(^T\) in BALB/c mice

The MLD for *B. mallei* strain ATCC 23344\(^T\) in BALB/c mice by the aerosol route was 1859 c.f.u. *B. mallei* strain ATCC 23344\(^T\), delivered by the intraperitoneal route, was non-lethal to BALB/c mice at doses up to and including 10\(^6\) bacteria for up to 35 days post-infection (M. S. Lever, unpublished observation); however, an intraperitoneal LD50 of 7 \(\times 10^5\), using the same strain of *B. mallei* in BALB/c mice, has been reported previously (Fritz et al., 2000). It has been shown that the virulence of *B. mallei* can be increased by successive animal passage (Minett, 1930); however, the strain used in this study had not undergone any such passage. This may explain the discrepancy of MLD data in the present study compared to those of other groups. Increased lethality achieved with aerosol compared to intraperitoneal challenge has also been observed with the closely related bacterial species *B. pseudomallei* (M.S. Lever, unpublished observation; Jeddeloh et al., 2003). A possible cause for this route-dependent susceptibility may be the large lung epithelial surface area, with associated macrophages and plentiful blood supply. This would result in efficient uptake of bacteria by macrophages and neutrophils and the subsequent dissemination of bacteria throughout the body. In contrast, a smaller cellular surface area with a more limited blood supply, such as that in the peritoneal cavity, could result in less efficient uptake and transport of bacteria to local lymph nodes.

Bacterial cell counts in tissues

Bacterial counts in lung, liver and spleen from days 1–14 post-infection are shown in Fig. 1. At 1 h post-infection, the lungs contained approximately 5.0 \(\times 10^3\) bacteria. The number of bacteria increased to approximately 1.0 \(\times 10^4\) bacteria by 18 h post-infection. Between 18 and 24 h post-infection, a 100-fold decrease was detected in the number of bacteria, followed by a sharp increase by 2 days post-infection. Thereafter, the number of bacteria increased.
The presence of bacteria in the blood at 18 h post-infection and foci of infection observed in liver and spleen from 24 h post-infection suggested the rapid spread of infection via the bloodstream during bacteraemia or septicaemia. The presence of lesions in the spleen and liver and their absence in the brain and kidney suggested that bacteria in the blood were taken up by phagocytic cells and that some of these phagocytosed bacteria were able to persist and multiply to form secondary foci of infection. No bacteria were cultured from the blood before 18 h post-infection; however, bacteria were cultured from both spleen and liver by 12 h post-infection. This suggested that although secondary foci of infection were established by haematogenous spread, there were very low numbers of bacteria in the blood that were undetectable. This finding was consistent with *B. mallei* infection in hamsters (Fritz et al., 1999), where bacteraemia followed 24 h after the detection of bacteria in spleen and liver.

Studies on *B. mallei* aerosol infection in laboratory animals are limited. The infection of BALB/c mice by the aerosol route with a highly virulent strain of *B. mallei* (LD50, 34.4 cells by the aerosol route) has been reported (Alekseev et al., 1994) and the general course of infection and mortality data are in agreement with the findings of the present study. The initial stage of the disease described the localization of the pathogen in the upper and lower sections of the respiratory tract and transportation of bacteria within alveolar macrophages to regional lymph nodes. Multiplication of the organisms occurred within lung tissue in the first 3–12 h post-infection, as was seen in the present study.

Mortality due to *B. mallei* infection occurred between days 4 and 10 post-infection.

### Histopathological analysis of *B. mallei*-infected tissues

Acute, focal, necrotizing alveolitis and pneumonia were seen in the lungs at 24–96 h post-infection. These lesions were apparent as numerous foci of consolidation, due to infiltration of alveolar walls and spaces by large numbers of neutrophils and smaller numbers of macrophages (Fig. 2). Necrotic cells in alveolar spaces were evident as a mixture of strongly eosinophilic and strongly basophilic amorphous material. Compared to non-infected control animals, generalized thickening of alveolar walls, dilation of bronchi and alveolar emphysema were noted in animals killed 48 h post-infection. Focal bronchitis was present at 72 and 96 h post-infection, together with focal peri-bronchial inflammation.

Extensive areas of lung consolidation were seen from 5 days after challenge onwards (Fig. 3). Alveolar spaces were filled with neutrophils and macrophages, but necrotic cells were much reduced in number. Epithelial cells that lined inflamed bronchi and bronchioles were hypertrophied and exhibited eosinophilic cytoplasm. Arteritis and peri-arterial inflammation were noted from 5 days after challenge until the end of the experiment.
Bronchiectasis, the dilation of bronchi and bronchioles to form cavities filled with pus, was noted at 7 days post-infection (Fig. 4). The pus comprised mucus, neutrophils, macrophages and sloughed epithelial cells. Many cells were necrotic. Foci of pleuritis were seen in animals killed 8 days after challenge; predominant inflammatory cells were lymphocytes and macrophages, with small numbers of neutrophils.

Lesions of variable severity were noted in the lungs of a mouse killed 14 days post-infection. One lobe was unremarkable, diffuse thickening of alveolar walls was noted in a second and extensive consolidation was present in a third lobe. Bronchial and arterial structures were obliterated completely in the consolidated tissue.

One small focus of necrosis was noted in the liver of a mouse killed 24 h post-infection. Mild intracytoplasmic vacuolation of hepatocytes, possibly due to lipid, and nuclear enlargement were observed in mice killed 48 and 72 h after challenge; the liver of the mouse killed at 72 h contained numerous foci of acute necrotizing hepatitis (Fig. 5).

At 96 h post-infection, the size of hepatocyte nuclei was less variable and portal areas were mildly infiltrated by lymphocytes. In the liver of this mouse, small foci of mixed inflammatory cells and large foci of necrosis were common and a diffuse increase in inflammatory cells in sinusoids was noted. Small foci of mixed inflammatory cells, foci of large mononuclear cells (probably macrophages), focal necrosis and vacuolation of hepatocyte cytoplasm were seen in mice killed at 5, 7, 8 and 14 days post-infection.

Foci of acute splenitis were noted in mice killed at 2, 3, 4 and 5 days after challenge. In mice killed 7, 8 and 14 days after challenge, splenic red pulp was expanded by the presence of numerous large, pale-staining, mononuclear cells with large open nuclei. Peri-arterial lymphoid sheaths were defined less clearly and contained pale-staining, lymphoblast-like cells. The number of megakaryocytes was increased and some appeared to be degenerate. Abnormalities were not detected consistently in the brain or kidney of mice that had been infected with *B. mallei*.

Histopathological evidence suggested that there was a trend...
for inflammatory processes in the lung to become subacute or chronic and this was associated with the development of extensive consolidation. In liver and spleen, it was impossible to determine whether lesions in chronically infected mice would have continued to extend, resulting in death, or would have resolved, allowing mice to survive. It is known that \( B. \) \textit{mallei} can be cultured after long periods of time following infection from mice, hamsters and guinea pigs (Miller \textit{et al.}, 1948); in human cases of glanders, the disease can be prolonged and is invariably fatal if not treated effectively. Similarly, \( B. \) \textit{pseudomallei}, a closely related species, is known to manifest as either acute or chronic disease in humans and can remain latent for prolonged periods of time (Sanford, 1995; Currie \textit{et al.}, 2000).

Studies on systemic infection (intraperitoneal) reported that splenomegaly was the principal gross pathological lesion and reticuloendothelial-rich tissues, such as spleen, liver and bone marrow, were particularly susceptible to localization of the bacteria. Tissue tropism for spleen and, to a lesser extent, liver, was noted in the present study; however, the intraperitoneal mouse model of glanders reported no glanders-related changes in the lungs of mice (Fritz \textit{et al.}, 2000). This was in contrast to the present study, where the predominant pathology was observed in the lungs, presumably as this was the route of infection. In addition, other reports of \( B. \) \textit{mallei} infection in the BALB/c mouse (following subcutaneous inoculation) describe pneumonic foci (Ferster & Kurilov, 1982).

**Immunocytochemical analysis of \( B. \) \textit{mallei}-infected tissues**

Results of immunostaining of lung, liver and spleen tissues with mAb 3VIE5 were summarized in Table 1. Immunolabeling of paraffin-embedded tissues with mAb 3VIE5, which recognized exopolysaccharide antigen, indicated that \( B. \) \textit{mallei} antigen was present primarily in lung tissue. Staining became more intensive and extensive over time as infection progressed. On days 1, 2 and 3 post-infection, antigen was confined to foci of acute necrotizing pneumonitis (Fig. 6) and was located primarily within the cytoplasm of macrophages and neutrophils associated with areas of consolidation. The level of antigen, as determined by subjective scoring of the intensity of staining, ranged from weak at day 1 post-infection to moderate by day 3 post-infection. Antigen was generally seen within individual leukocytes and macrophages, but individual bacteria could not be identified. In a hamster model of glanders (Fritz \textit{et al.}, 1999), little evidence of bacterial killing was found within viable leukocytes. Most degenerated bacilli were observed within degenerating or necrotic leukocytes, which suggested that \( B. \) \textit{mallei} was able to remain viable intracellularly for significant periods of time. At 7 days post-infection, bronchiectasis was evident and antigen was present in moderate quantities within the mucus that filled the bronchiectatic cavities. In addition, nuclei of adjacent bronchoepithelial cells stained strongly for antigen. At the end of the experiment (by day 14 post-infection), mucopus associated with bronchiectasis stained strongly for antigen and strong staining was evident in adjacent viable tissue (Fig. 7).

\( B. \) \textit{mallei} antigen was detected in liver tissue only on days 3 and 4 post-infection; staining was weak and associated with foci of acute necrotizing hepatitis. Antigen was not detected in liver from day 4 post-infection until the end of the experiment at day 14 post-infection.

\( B. \) \textit{mallei} antigen was not detected in spleens on days 1–7 post-infection, but was present in spleens taken at 14 days post-infection. At this time-point, the intensity of staining was strong but confined to foci of acute splenitis.

After initial infection of the spleen at 18 h post-infection, bacterial numbers in the spleen decreased at 24 h post-

infection before increasing 10,000-fold by 4 days post-infection. This initial decrease in bacterial numbers has been noted previously in hamsters (Fritz et al., 1999), where it has been suggested that *B. mallei* is killed and lysed relatively early in the disease process within certain tissues, such as spleen, and that components of degraded bacteria continue to promote leukocyte chemotaxis and lesion development. In this study, no *B. mallei* antigen-specific immunostaining was detected in spleen tissue until the end of the study at day 14 post-infection. This was surprising, as bacterial numbers at 4 days post-infection were as numerous as those at 14 days post-infection [approx. 5000 c.f.u. (ml homogenized tissue)]⁻¹. An increase in capsular antigen that originated from degraded bacteria may have been responsible for the immunolabelling seen at 14 days post-infection. Alternatively, production of exopolysaccharide by *B. mallei* has been proposed as a virulence determinant in hamsters (DeShazer et al., 2001) and guinea pigs (Popov et al., 1991, 2000); the increase in intensity of staining may reflect the increase in exopolysaccharide produced by each bacterial cell.

Strong immunostaining seen at 14 days post-infection in both lung and spleen may indicate that both tissues are possible sites for the organism to remain latent.

In this study, BALB/c mice proved to be susceptible to *B. mallei* infection when the organisms were delivered as small-particle aerosols; the disease seen closely resembles the acute form of the disease in natural *B. mallei* infection in humans, characterized by rapid onset of pneumonia, bacteraemia, pustules and death within days.
