INTRODUCTION
The genus Cardiobacterium was created in 1964, including one species, Cardiobacterium hominis, a fastidious, pleomorphic, Gram-negative bacillus (Slotnick & Dougherty, 1964). The genus Cardiobacterium is one of the members of the HACEK group (Das et al., 1997; Lang & Morris, 2002; Slotnick & Dougherty, 1964), a group of Gram-negative bacteria that includes Haemophilus spp., Aggregatibacter actinomycetemcomitans, C. hominis, Eikenella corrodens and Kingella kingae. Before 2004, C. hominis was the only Cardiobacterium species known. Cardiobacterium valvarum was first identified as a novel species by Han et al. (2004) and is a rare aetiological agent of infective endocarditis. Until now, only seven cases of C. valvarum infective endocarditis have been reported in the literature (Vanérvková et al., 2010; Geissdörfer et al., 2007; Bothelo et al., 2006; Han, 2005; Han & Falsen, 2005; Han et al., 2004; Hoffman et al., 2010). In this study, we report a case of infective endocarditis of the mitral valve, rupture of chordae and prolapse of P1 and P2 in addition to a fluttering excrescence caused by C. valvarum and an analysis of 11 strains of Cardiobacterium species, four of C. hominis and seven of C. valvarum.

CASE REPORT
A 64-year-old man was admitted to the local hospital due to increasing dyspnoea and severe mitral insufficiency. He worked as a music teacher. He had a 1-year history of moderate mitral valve prolapse and mitral insufficiency diagnosed by echocardiography, and was an outpatient at the cardiology department of the hospital. During the previous year, he had become tired easily and experienced slight dyspnoea when bicycling uphill.
Eight weeks prior to admission, the patient received a tooth implantation on which occasion he did not receive antibiotic prophylaxis. For the previous several weeks, the patient had experienced febrile episodes, profuse sweating and night shiver episodes. A new episode occurred the night before admission, in addition to low blood pressure and fever of 39.9 °C. On admission, he was afebrile with a blood pressure of 130/60 mmHg. Auscultation revealed a grade 2 of 6 systolic heart murmur. A light oedema of both ankles was noted. Laboratory examinations showed haemoglobin of 65 g l\(^{-1}\), leukocyte count of 9.4 \(\times\) 10\(^9\) l\(^{-1}\), C-reactive protein of 79 mg l\(^{-1}\), thrombocyte count of 88 \(\times\) 10\(^9\) l\(^{-1}\), basic phosphatase of 127 U l\(^{-1}\) (normal range 35–105), bilirubin of 36 \(\mu\)mol l\(^{-1}\) (normal range 5–25) and lactate dehydrogenase of 271 U l\(^{-1}\) (normal range 105–205). Ultrasound examination of the abdomen was normal. Six blood culture bottles (Bactec Plus aerobic/F bottles) were taken and empirical therapy with intravenous penicillin 5 million units four times daily and gentamicin 120 mg twice daily was initiated.

Four out of the six blood culture bottles taken on initial admission yielded growth of Gram-negative rods after 3 days of incubation. Penicillin was changed to intravenous cefuroxime (1.5 g three times a day), and the gentamicin treatment was continued. Echocardiography revealed severe mitral insufficiency with mitral valve prolapse, rupture of chordae and prolapse of P1 and P2 in addition to a fluttering excrescence. Three days after admission, the patient was moved to the cardiology department at a highly specialized hospital for further treatment.

Ten days after admission, the Gram-negative rods were eventually identified as \textit{C. valvarum}. Cefuroxime treatment was changed to ceftriaxone 1 g twice daily.

The patient was operated on 22 days after admission. The mitral valve was replaced with a mechanical valve and neochordae were inserted. While culture was negative, bacterial DNA from \textit{C. valvarum} was found on the mitral valve by partial 16S rRNA gene sequence analysis. The patient received 6 weeks of antibiotic treatment of which 2 weeks was post-operative. The patient was discharged clinically well 78 days after admission without paraclinical signs of infection.

**METHODS**

**Bacterial culture and strains.** The case strain and 10 other strains examined are listed in Table 1. The case strain was isolated from blood samples.

**Phenotypic characterization.** Strains were cultured on 5 % and 10 % horse-blood agar and chocolate agar plates. Incubation was at 37 °C in ambient air with and without a supplement of 5 % CO\(_2\). Growth at 22 °C was read for 6 days. Anaerobic growth, on a prereduced medium, was read after incubation for 6 days in an anaerobic jar (70 % N\(_2\), 20 % H\(_2\) and 10 % CO\(_2\)). Motility, cellular morphology and Gram-stained smears of all bacterial strains were examined by light microscopy. Phenotypic characterization of strains was mostly conducted using conventional methods as recommended by the Danish Reference Group for Identification of Clinically Important Bacteria (Bruun et al., 1999). \(\beta\)-Galactosidase production was detected by the method of Kilian & Bülow (1976) with 0.2 % o-nitrophenyl-\(\beta\)-galactoside. All strains were also tested with an API 20NE kit and the Vitek 2 \textit{Neisseria–Haemophilus} identification card and read according to the manufacturer's instructions. Antimicrobial susceptibility testing was performed with Neo-Sensitabs (Rosco) on Danish Blood Agar using breakpoints according to the Clinical and Laboratory Standards Institute for \textit{Haemophilus} species (www.rosco. dk) and for tigecycline using Etest. The case strain was also examined by Etest for susceptibility to selected treatment-relevant antibiotics.

**Partial 16S rRNA gene sequencing.** Partial 16S rRNA gene sequencing of bacterial strains followed by \textit{BLAST} examination was performed using two amplification primers, BSF8 and BSR1407, producing a 1399 bp fragment; these fragments were sequenced both ways (Christensen et al., 2005). For partial 16S rRNA sequencing of bacterial DNA in valve tissue PCR was done on DNA extracted by a QIAamp DNA Mini kit (Qiagen) using the primers BSF8 and BSR534, which produce a 526 bp product (Christensen et al., 2005). All fragments were sequenced both ways. The edited sequences were compared to deposited sequences in the NCBI ‘bacteria’ database (\textit{BLAST} examination) and evaluated for the best and second best taxon matches taking into consideration the percentage identity (number of identical bases between the query and the subject sequence in the database), Max scores (indication of alignment concordance) and E-values (indication of statistical significance of a given alignment). Partial 16S rRNA sequencing of bacterial DNA in valve tissue was done as previously described (Koch et al., 2010).

**RESULTS**

**Phenotypic characterization**

**Growth characteristics.** The phenotypic features of the 11 strains were compared. When incubated in ambient air supplemented with 5 % CO\(_2\) on 5 % and 10 % horse blood agar as well as on chocolate agar, all strains grew with colonies <1 mm after 24 h incubation and with grey colonies sized 1–2 mm after 48 h incubation, except for four strains [CCUG 12990, CCUG 31208, CCUG 48245\(^T\) (\textit{C. valvarum}) and CCUG 31207 (\textit{C. hominis})], which had not grown after 24 h, but grew with small colonies sized <1 mm after 48 h. Colonies were similar, being small, round, opaque, smooth, grey and glistening. For all strains there was slight \(\alpha\)-haemolysis on blood agar plates. There was no difference in colony morphology between \textit{C. valvarum} and \textit{C. hominis}, and no difference in morphology on 5 % and 10 % blood agar and chocolate agar plates. Strains were Gram-negative rods that varied in size, typically being pleomorphic and some had pointed ends. All strains were facultatively anaerobic and non-motile. Some strains had an acidulous smell.

**Biochemical reactions.** All strains were oxidase-positive, catalase-negative and nitrite reductase-negative, except for one \textit{C. hominis} strain (CCUG 31207) which was nitrite reductase-positive. All strains produced acid from glucose (no gas), maltose, mannitol, mannose, sorbitol and sucrose, but not from lactose or galactose. Eight out of eleven strains were indole-positive. Ten out of eleven
strains were sucrose-positive. All strains were tested with an API 20NE kit, but there were no positive reactions. Table 2 shows the positive and variable biochemical reactions of the 11 strains in the Vitek 2 Neisseria–Haemophilus identification card wells. Eleven wells containing the following substances were read as negative for all strains: arginine arylamidase, glycogen, \( \beta \)-galactopyranoside indoxyl, malto- triose, L-proline arylamidase, ornithine decarboxylase, L-lysine-arylamidase, D-galactose, phosphorylcholine, urease, D-malate and D-xylose. Three reactions were positive for all 11 strains in the Vitek 2 API 20NE kit, but there were no positive reactions. Table 2 shows the positive and variable biochemical reactions of the 11 strains examined and the results of near full-length (1399 bp) 16S rRNA gene sequence analysis.

(MIC 0.004 μg ml⁻¹) and meropenem (MIC 0.004 μg ml⁻¹).

16S rRNA gene sequencing and phylogenetic analysis

Table 1 shows the results obtained by 16S rRNA gene sequencing and subsequent BLAST examination of the bacterial strains. Seven and four strains were identified as C. valvarum and C. hominis, respectively. The phylogenetic trees (Fig. 1a, b) show that strains within the two species were very similar and that the two species were well separated. C. valvarum strains had sequence similarities ranging between 98 and 100 %, Max scores between 2217 and 2758, and Max score differences to the next best taxon match, which for all strains was C. hominis, ranging from 212 to 412. C. hominis strains had sequence similarities ranging between 98 and 100 %, Max scores between 2423 and 2435, and Max score differences to the next best taxon match, which for all strains was C. valvarum, ranging from 200 to 298.

Partial 16S rRNA gene sequence examination of the surgically removed valve showed C. valvarum as best match with a Max score of 857 and number of identities being 469 out of 471, with C. hominis as second best match (score 719 bits, 449 of 476 identities).

DISCUSSION

Infective endocarditis is most commonly caused by Staphylococcus aureus, coagulase-negative staphylococci and streptococci (McDonald, 2009). Up to 3 % of cases of infective endocarditis are attributable to HACEK organisms (Das et al., 1997). Bacteria in this group have in common a culture requirement for an enhanced CO₂ atmosphere and the ability to infect human heart valves. C. valvarum is also a new member of the HACEK group and was first reported by Han et al. (2004). The first reported strain was grown from the blood of a 37-year-old man who had insidious endocarditis with a sudden rupture of a cerebral aneurysm. Characterization of the organism through phylogenetic and phenotypic analyses revealed a novel species of Cardiobacterium, Cardiobacterium valvarum.

At least seven previous cases of infective endocarditis caused by C. valvarum have been reported worldwide (Vaněrková et al., 2010; Geissdörfer et al., 2007; Bothelo et al., 2006; Han & Falsen 2005; Han et al., 2004; Hoffman et al., 2010). In six reported cases, blood cultures yielded growth of C. valvarum strains and in one case bacteriological diagnosis was made by 16S rRNA gene amplification, sequencing and BLAST examination of valvular tissue alone; in two cases, bacteriological diagnosis was obtained by a positive blood culture as well as by molecular examination of valvular tissue, as in the case described here. In five of the previously described cases, the aortic valves were involved (in one case in addition to the tricuspid valves), and in one case, details were not given. Of the five cases of aortic involvement, one was fatal (infection in a prosthetic valve) and valve replacement was performed in three cases. The ruptured intracranial aneurysm described by Han et al. (2004) illustrates the propensity of C. valvarum to cause an embolism, a feature it has in common with C. hominis as well as its tendency to cause exceptionally low grade and insidious infections (Das et al., 1997).

The present case adds to the description of the infective potential of C. valvarum as it was the mitral valve that was harmed and rupture of chordae occurred. Valve replacement was needed and neochordae were inserted. The patient described in the present report had a 1-year history of a moderate mitral valve prolapse and mitral insufficiency diagnosed by echocardiography and had received a tooth implantation 8 weeks prior to admittance. Most reported C. valvarum infective endocarditis cases were related with periodontal diseases. Four of the strains were isolated from the oral cavity of patients with periodontitis, subgingival pockets or tooth plaque, further supporting...
Fig. 1. (a) Phylogenetic tree determined on the basis of the sequences of the 16S rRNA gene obtained by the unrooted neighbour-joining method in the MEGA (version 4.0) program package. The scale bar indicates the evolutionary distance between the sequences determined by calculation of the per cent sequence divergence. It clearly divides the two species *C. hominis* and *C. valvarum* into two groups. (b) Minimal evolution algorithm (suppressed) obtained by using the MEGA (version 4.0) program and based on the 16S rRNA gene. It clearly divides the two species *C. hominis* and *C. valvarum* into two groups.
that the most probable way of the bacterium entering the bloodstream is via the upper respiratory tract.

*C. valvarum* has been described as a fastidious Gram-negative bacillus that grows better on sheep blood agar than on chocolate agar. In contrast to *C. hominis*, *C. valvarum* should grow more slowly, be non-haemolytic on sheep blood agar, and not utilize sucrase, maltose or mannitol (Han et al., 2004). However, phenotypic tests may not always allow the two *Cardiobacterium* species to be distinguished and different phenotypic methodologies may give different results as seen with regard to results obtained for acid production from sucrase, maltose and mannitol. In such cases, genotypic identification is a good help and should be performed. Phenotypic characterization analysis shows that *C. valvarum* and *C. hominis* have many reactions in common. When using conventional methods, the only difference we found between these two *Cardiobacterium* species was acid production from raffinose, which for *C. hominis* strains was positive. However, no acid was produced from raffinose by *C. hominis* in the report by Han & Falsen (2005). It is difficult to distinguish *C. valvarum* and *C. hominis* from their phenotypic characterization. No reactions were positive among reactions included in the API 20NE kit. Automatic reading when using the Vitek 2 Neisseria–Haemophilus Identification Card did not separate the two species as the database only includes *C. hominis*. However, results from the well containing phenylphosphonate seem useful as a test separating the two species. One research group (Geissdörfer et al., 2007) used the API NH identification system, which is commonly used for identification of *Haemophilus* species and *Neisseria* species of clinical importance. The outcome of the reactions was well defined, but resulted in a misidentification as *Haemophilus paraphaenae*. Therefore, they concluded that API NH may be used for determination of key reactions in the case of fastidious Gram-negative rods such as *C. valvarum*, but for final identification, molecular tools, e.g. 16S rRNA gene sequence analysis, are indispensable. The present data show that *C. valvarum* and *C. hominis* are susceptible to many antibiotics. These data are consistent with previous data also showing sensitivity to most used β-lactams. The patient described here was treated successfully with cefuroxime and ceftriaxone.

Conventional methods for microbial identification require the recognition of differences in morphology, growth, enzymic activity and metabolism to define genera and species. As seen above, *C. hominis* and *C. valvarum* have many similarities and few different reactions. Full-length and partial 16S rRNA gene sequencing methods have emerged as useful tools for identifying phenotypically aberrant and relatively non-aberrant micro-organisms and have made major contributions to taxonomy within the last decades. When performing short (526 bp) and near full-length (1399 bp) 16S rRNA gene sequence analysis all examined strains convincingly were allocated to either *C. hominis* or *C. valvarum*. These results are in accordance with the results reported in the individual case reports. Phylogenetic trees based on 16S rRNA gene sequence analysis clearly divided the examined strains into the two species. One group (Petti et al., 2005) examined three blood-culture strains received for further identification, of which one turned out to be *C. valvarum*, where the initial phenotypic identifications were erroneous. The authors conclude that this may have misled clinicians, and potentially impacted patient care; 16S rRNA gene sequencing is a more objective identification tool, unaffected by phenotypic variation or technologist bias, and has the potential to reduce laboratory errors. In two of the case reports, the presence of *C. valvarum* 16S rRNA gene sequences was also demonstrated in removed valvular tissue, as in our case.

In conclusion, we describe what is believed to be the eighth case of infective endocarditis due to *C. valvarum*, and the first case affecting the mitral valves and with ruptured chordae. Clinical microbiologists and physicians should be aware that *C. valvarum* is a potential agent of infective endocarditis when HACEK strains are isolated from blood cultures. Our data show that *C. valvarum* and *C. hominis* strains have high phenotypic resemblance with few differentiating reactions, which makes us speculate that some of the early *C. hominis* strains identified by phenotypic methods might be *C. valvarum*. 16S rRNA gene sequence analysis has proved to be a very useful and reliable tool for identifying strains and confirming their presence in valvular tissue.
