Population structure and uropathogenic virulence-associated genes of faecal *Escherichia coli* from healthy young and elderly adults

Tara L. Vollmerhausen, Nubia L. Ramos, Aycan Gündoğdu, Wayne Robinson, Annelie Brauner and Mohammad Katouli

We investigated the population structures of faecal *Escherichia coli* in 30 healthy young adults (13 males and 17 females) aged between 20 and 45 years and 29 elderly adults (14 females and 15 males) aged between 65 and 77 years. In all, 1566 strains were typed with the PhPlate system and grouped into biochemical phenotypes (BPTs). Strains with shared BPTs were further typed using randomly amplified polymorphic DNA analysis. Forty-four per cent of the strains were shared between two or more age and gender groups. Elders had a significantly higher (P < 0.001) number of BPTs (mean ± standard error 3.3 ± 0.27) than younger groups (1.82 ± 0.27). Phylogenetic affiliation and virulence-associated genes (VAGs) of the strains showed that more than 80% of the strains belonging to dominant types belonged to phylogroups B2 and D. Amongst dominant BPTs, phylogenetic group A was significantly associated with females (P < 0.0001), and elders were more likely to carry group D (P < 0.0124). Elderly males had a higher prevalence of VAGs than young males (P < 0.0001) and young females (P < 0.0005). We conclude that there is a lower prevalence of *E. coli* with uropathogenic properties in healthy young adults than in elders.

INTRODUCTION

Urinary tract infection (UTI) is one of the most common diseases of young women worldwide, with 60% of women experiencing at least one episode during their lifetime (Foxman et al., 2000). Young women are more susceptible to UTI than men, with the shortness of the female urethra a predisposing factor to infection (Foxman, 2003). Other factors also increase a woman’s likelihood of infection, including sexual activity, oral contraceptives, oestrogen deficiency, diabetes, obstructing lesions and genetic factors such as blood group secretor status (Harrington & Hooton, 2000; Scholes et al., 2000). Amongst the causative agents of UTI, *Escherichia coli* is responsible for >90% of cases and is almost always found amongst the faecal flora of the same host, although these bacteria may be harboured in the vagina or periurethra (Czaja et al., 2009; Moreno et al., 2008).

The intestinal niche can harbour a range of commensal and pathogenic *E. coli* strains and has been elucidated as a reservoir of strains capable of causing extraintestinal infection. It is widely accepted that uropathogenic *E. coli* (UPEC) strains largely belong to phylogenetic group B2, and to a lesser extent group D, and intrinsically harbour a range of virulence genes (Johnson et al., 2005; Moreno et al., 2008; Picard et al., 1999; Sannes et al., 2004). Commensal strains, on the other hand, generally belong to phylogenetic groups A and B1, and are associated less frequently with disease (Bingen et al., 1998; Boyd & Hartl, 1998; Duriez et al., 2001; Johnson & Stell, 2000). All of these groups are commonly isolated from the gut of healthy humans, with groups B2 and D commonly associated with dominant populations (Moreno et al., 2009; Zhang et al., 2002). UPEC strains have virulence-associated genes (VAGs) that facilitate their adherence to the opening of the urinary tract and allow them to ascend to the bladder to cause UTI. Type 1 fimbriae are important for initiating adhesion, although it is the P-pili that are regarded as an essential
virulence factor for adhesion of E. coli to the uroepithelium (Abraham et al., 2001; Arthur et al., 1989; Wright et al., 2007). Nonetheless, these VAGs also have an important role in survival of these strains within the gut, enhancing their colonization as dominant strains (Tullus et al., 1992; Wold et al., 1988, 1992). We hypothesized that in addition to the predisposing factors for UTI mentioned above, UPEC strains may be more dominant in the intestinal E. coli populations of healthy young and elderly females than in those of males in the same age groups, making females more vulnerable to UTI. Furthermore, the population structure, diversity and prevalence of specific VAGs associated with UPEC among E. coli from healthy young and elderly adults is not well understood. The aim of this study was therefore to investigate the prevalence of uropathogenic VAGs among faecal E. coli from healthy young and elderly adults and to determine whether differences in E. coli population structures in the gastrointestinal tract could indicate predisposition to UTI.

METHODS

Subjects. This study was approved by the University of the Sunshine Coast Human Research Ethics Committee and participation entailed providing informed consent and returning a self-collected faecal swab. Between August and November 2009, a total of 59 healthy community-dwelling individuals were registered for this study. These included 17 healthy young females aged between 21 and 45 years (mean age ± standard deviation, 33.2 ± 9.7), 13 healthy young males aged between 20 and 45 years (26.5 ± 8.9), 14 healthy elderly females aged between 65 and 77 years (67.9 ± 3.5) and 15 healthy elderly males aged between 65 and 79 years (72.1 ± 5.2). Young subjects were recruited after an invitation email to staff and students at the University of the Sunshine Coast community. Elderly subjects were recruited via the University of the 3rd Age Community Group at University of the Sunshine Coast. Care was taken to recruit subjects that were not from the same household but lived in the Sunshine Coast region of Queensland, Australia. None of the subjects had a symptomatic UTI in the preceding 6 months, or had taken any antibiotics or commercially available probiotics in the 3 months prior to participating in the study. In female groups, an additional criterion was the lack of known pregnancy.

Isolation and confirmation of E. coli strains. Each volunteer returned a self-collected faecal swab inserted into Amies transport medium containing charcoal. Swabs were kept at 4 °C and streaked directly onto MacConkey agar no. 3 and membrane faecal coliform agar within 24 h of collection. Plates were incubated for 24 h at 37 °C and 28 E. coli-like colonies (where possible) were randomly selected and tested. This number of colonies provide >90% chance of detecting minor clones amongst the host E. coli faecal population as previously described (Schlager et al., 2002). Extraction of chromosomal DNA was done by growing a single colony of the isolates in Luria–Bertani broth overnight and collecting pellet in 200 μl sterile MilliQ water and boiling at 100 °C for 15 min. In all, 1566 putative E. coli strains were collected and subjected to confirmatory tests using PCR amplification of the universal stress protein (upA) gene as previously described (Chen & Griffiths, 1998).

Biochemical fingerprinting. All strains were typed using a high-resolution biochemical fingerprinting method (PhPlate system), specifically developed for E. coli strains (PhP-RE; Bactus). The fingerprinting method was performed according to the manufacturer’s instructions. Briefly, E. coli colonies were suspended in the first well of each row containing 325 μl growth medium comprised of 0.011 % (w/v) bromothymol blue and 0.1 % (w/v) protease peptone. Aliquots of 25 μl of bacterial suspensions were transferred into each of the other 11 wells containing 150 μl growth medium. Plates were then incubated at 37 °C and read at intervals of 7, 24 and 48 h. Images of plates at corresponding times were scanned using a HP Scanjet 4890 scanner. After the final scan, the PhPlate software (PhPWin4.2) was used to create absorbance data from the scanned PhP-RE plate images. After the final reading of the plate images, the mean of the absorbance values from all individual readings was calculated for each reagent, creating the biochemical fingerprint for each isolate (Landgren et al., 2005). Similarity among the isolates was calculated as a correlation coefficient, and clustered according to the unweighted pair-group method using arithmetical averages to yield a dendrogram. An identity level of 0.965 was established based on the reproducibility of the system after testing 60 isolates in duplicate. Isolates showing similarity to each other above the identity level were regarded as identical and assigned to the same biochemical phenotype (BPT). BPTs containing more than one isolate were called common (C) BPTs and those with one isolate were named single (S) BPTs. Diversity among the isolates was calculated as a diversity index using Simpson’s index of diversity. All data handling, including calculations of correlations and coefficients, diversity indices as well as clustering were performed using the PhPlate software version 4002 (PhPlate).

Randomly amplified polymorphic DNA (RAPD) analysis. Strains that were identical in two or more individuals or groups as determined by the biochemical fingerprinting method were further typed by RAPD-PCR. The RAPD analysis was performed with the KG (5’-ACACCCACGGAGAAGAA-3’) primer (Ramos et al., 2010). The PCR was carried out in a 50 μl volume containing 31.3 μl sterile MilliQ water, 6 μl 10× PCR buffer, 3.8 μl 50 mM MgCl2, 1 μl 10 mM deoxynucleoside triphosphates (dNTPs) (Fisher Biotec), 0.4 μl Taq polymerase (Bioline), 6 μl primer (20 pmol μl−1) (Invitrogen) and 1.5 μl DNA. PCRs were amplified as previously described (Ramos et al., 2010) and products were size separated by electrophoresis in 2.2 % agarose stained with ethidium bromide at 90 V for 180 min. Molecular mass markers (100 bp and 1 kb) were used in all of the experiments. Similarity between the banding patterns was compared visually and divided into similarity groups (RAPD types). Strains belonging to the same C-BPT and sharing the same RAPD pattern were regarded as common types (CTs) while those with different RAPD patterns but an identical BPT or identical RAPD pattern but different BPTs were regarded as single types.

Phylogenetic grouping and VAGs. All confirmed E. coli strains were tested for their phylogenetic groups (A, B1, B2 and D) using a triplex PCR method for chuA, yjaA and TSPE4.C2 as previously described (Clermont et al., 2000). The presence of the ibaA gene among Clermont phylogenetic group D (i.e. chuA- and TSPE4.C2-positive and yjaA-negative) was also investigated and those strains harbouring ibaA genes were regarded as belonging to phylogenetic group B2 as described before (Gordon et al., 2008).

Strains were also tested for 12 VAGs known to be associated with UTI. These included adhesin genes for P-pili (papA, papE, papC, papG allele II and papG allele III) and type 1 fimbriae (fimH); toxin genes α-haemolysin (hlyA) and cytotoxic necrotizing factor 1 (cnf1); siderophore genes ferric aerobactin receptor (iusA) and a catecholate siderophore (inoS, col); K1 capsule gene (kpsMT K1) and group II capsular polysaccharide synthesis gene, e.g. K1, K5 and K12 (kpsMT II). Genes were grouped into four multiplex primer sets and two uniplex sets in a modified method to that previously described (Johnson & Stell, 2000), with appropriate positive and negative controls. The multiplex PCRs consisted of 2.5 μl 10× reaction buffer, 5 μl 2 mM dNTPs, 2.5 μl 25 mM MgCl2, 0.3 μl of each primer from

Table 1. Statistical analysis. Factorial analysis of variance was used to compare diversity and abundance of BPTs between age and gender groups and residual analyses were used to investigate the assumptions of normality and homogeneity of variances. A square root transformation was applied to meet the assumption of homogeneity of variances for the number of BPTs. The numbers of VAGs per dominant and minor BPTs between the phylogenetic groups and gender and age categories. When there was a significant interaction of effects, we partitioned the analysis and applied the Benjamini–Hochberg method to moderate the false discovery rate (Waite & Campbell, 2006).

RESULTS

BPT diversity amongst groups

Of the 1566 putative E. coli strains, 1541 were confirmed as E. coli using the uspA gene. Biochemical fingerprinting of these isolates yielded 112 C-BPTs comprising 1502 isolates and 39 S-BPTs. The number of BPTs found in each subject ranged from 1.7 ± 0.9 in young males to 3.8 ± 2.0 in elderly males (Table 1). There was a significant difference between elderly (3.3 ± 0.27 mean ± standard error) and younger (1.82 ± 0.27 subjects) (Fagegroup = 12.3, df = 1.55, P < 0.001). There were, however, no differences when the numbers of BPTs in the two genders were compared. Similarly, the diversity of E. coli strains found among elderly (0.35 ± 0.046) subjects was significantly higher than that found in younger subjects (0.20 ± 0.045) (Fagegroup = 4.97, df = 1.55, P < 0.05) (Table 1). Again, there was no difference between the diversity of E. coli strains among genders.

Phylogenetic groups

A total of 63 dominant BPTs were identified among all 59 subjects (four subjects had two dominant BPTs). Of these, 80% belonged to phylogenetic groups B2 and D (Table 2). The prevalence of phylogenetic group was dependent on age and gender (χ² = 8.19, df = 3, P < 0.0423). Partitioning the analysis indicated that gender was significantly associated with phylogenetic group A (χ² = 16, df = 1, P < 0.0001) (Table 2) and that only females carried E. coli belonging to this phylogenetic group. Elderly were more likely than young groups to be carriers of E. coli belonging to phylogenetic group D (χ² = 6.25, df = 1, P < 0.0124) (Table 2). There were no differences for phylogenetic groups B1 and B2 between different age and gender groups. Elderly subjects had significantly more minor BPTs than younger subjects (χ² = 121.0, df = 1, P < 0.0001) and phylogenetic group D had significantly more minor BPTs than

*Two dominant BPTs were found in two young females, one young male and one elderly male.
In this study, we used a high-resolution biochemical fingerprinting method specifically developed for typing of E. coli strains. The system has been shown to be as powerful as other molecular typing methods such as RAPD-PCR (Ramos et al., 2010) and ERIC-PCR (Ansaruzzaman et al., 2000) for typing of E. coli strains. Up to 28 colonies from each participant were tested, providing a greater than 90% chance of detecting minor clones amongst the host E. coli faecal population (Schlager et al., 2002). Based on this number of isolates, we found that elderly males had a greater diversity of E. coli strains than both young males and females. Increased diversity amongst dominant bacterial species has been observed in healthy elderly subjects (Saunier & Doré, 2002). One possible reason could be changes in the mucosal surfaces in elderly subjects as also suggested by others (Ouwehand et al., 1999). It has also been postulated that mucus in elderly subjects differs from that in young adults, containing more carbohydrates and less protein (Ouwehand et al., 1999). Furthermore, decreased mucus production amongst elderly subjects may expose more receptors on the gut epithelium as postulated before (Ouwehand et al., 1999).

All subject groups, except young males, carried populations of E. coli belonging to phylogenetic group D as the major gut population. Phylogenetic group B2 was the second dominant group for elders. Young females carried strains belonging to phylogenetic group D as their largest population; these intrinsically carry fewer extraintestinal virulence factors than those of groups B2 and D (Clermont et al., 2000; Johnson et al., 2001). Similarly, young males and, to a lesser extent, young females also carried strains belonging to group B1, which is also less associated with UTI. These results suggest that faecal dominance of an E. coli strain in healthy young females is not a predictor of UTI. Similar to this finding, Schlager et al. (2003) identified that amongst girls aged 3–6 years, the other groups ($\chi^2 = 118.5$, df=3, $P < 0.0001$). The tendency for E. coli to belong to group D was even more pronounced in elderly subjects ($\chi^2 = 31.5$, df=1, $P < 0.0001$).

**Distribution of strains among individuals**

Biochemical fingerprinting identified 63 dominant BPTs and 88 minor BPTs. These 151 BPTs were further typed using RAPD-PCR to confirm the clonality of the isolates by two typing methods (i.e. BPT/RAPD types). It was found that 50 BPTs, representing 44% of isolates ($n=674$) that were shared between two or more age and gender groups, belonged to 18 BPT/RAPD types (Fig. 1). These BPT/RAPD types were designated CTs. Of these, CT5 and CT14 constituted more than 24% of the shared isolates and all belonged to phylogenetic groups B2 and D. These CTs contained strains with the highest VAG scores (Fig. 1).

**Virulence traits**

Comparison of dominant and minor BPTs found that dominant BPTs (2.48±0.185) had significantly ($z=2.25$, $n=63$, 88, $P=0.0244$) higher VAG scores than minor ones (1.98±0.137). There was a significant difference in prevalence between the age groups ($\chi^2=22.13$, df=1, $P<0.0001$) and some VAGs occurred more frequently than others ($\chi^2=250.23$, df=12, $P<0.0001$) (Table 3). There was a slight, not significant, interaction between age and gender of subjects ($\chi^2=2.97$, df=1, $P<0.10$) (Table 3). A follow-up analysis found that the prevalence of VAGs was significantly higher in elderly males than in either young males ($P<0.0001$) or young females ($P<0.0005$) and higher in elderly females than in young males ($P<0.05$).

**DISCUSSION**

In this study, we used a high-resolution biochemical fingerprinting method specifically developed for typing of Uropathogenic E. coli in healthy adults.
Fig. 1. An unweighted pair-group method using arithmetical averages dendrogram showing comparison of 50 *E. coli* types shared between two or more individual volunteers of different age and gender groups as determined by biochemical fingerprinting and RAPD analysis. The 18 common types (CTs) are shown as CT1–CT18. The RAPD pattern of each CT is also shown. Strains that were highly similar but showed separate RAPD patterns were designated subtypes using letters. Percentage of the shared population and VAG scores are also shown. PGG, Phylogenetic groups; A/G, age and gender group (YF, young female; YM, young male; EF, elderly female; EM, elderly male).

dominant faecal clones with P-pili were less likely to be found in the urinary tract than minor clones. Interestingly, young females in our study carried lower numbers of E. coli with uropathogenic properties and lower VAG scores, although this was not a significant result due to the low sample size. This may indicate that other factors, such as shortness of urethra, sexual activity or oral contraceptives, are more important than the structure of dominant E. coli populations in young females for their susceptibility to UTI. Capsule antigen genes were the only genes found more frequently in females, although this was not a significant difference in this study. A larger sample size is needed to determine whether females carry more capsular antigen K1 strains than males. This was an interesting observation as the K1 antigen gene is a key VAG in extraintestinal pathogenic E. coli associated with neonatal meningitis (Öhman et al., 1995) and perhaps a higher number of faecal K1 strains in this group is associated with contamination and infection of neonates after birth.

Comparison of the E. coli types among the four groups showed that a high proportion, 44% of the E. coli tested in this study, were common among the groups with two major groups accounting for more than 24% of the shared populations. The fact that these CTs belonged to pathogenic groups B2 and D and had the highest VAG scores suggests that certain E. coli clones of the dominant flora of the gut of healthy individuals are better equipped to cause UTI. Alternatively, these strains may be better adapted for the intestinal niche (Diard et al., 2010). Contrary to our expectation, we found that clones with increased virulence factors were more prevalent among elderly males than among young females. It has to be noted that in our study we tested E. coli from a small number of individuals (between 13 and 17 individuals in each group) and therefore confirmation of such a finding requires testing more individuals.

In this study, elderly males had a significantly higher prevalence of the tested VAGs. Contrary to our initial hypothesis that young females might have highly virulent dominant E. coli as a predisposition to UTI, the elderly groups, especially males, showed a significantly higher prevalence of VAGs. This finding not only indicates that dominant E. coli populations in healthy young females may not be the main cause of UTI in this group, but helps to explain the reported higher prevalence of extraintestinal infections such as UTI and septicaemia in hospitalized elderly patients, especially males, as more virulent strains were carried by these groups (Kaye, 1980).

Our results showed that dominant E. coli strains have more VAGs than minor strains as previously reported (Moreno et al., 2009). Apart from their role in adhering to the urinary tract cells, P-pili have also been shown to bind to the intestinal tract, which enhances their colonization of the gut (Tullus et al., 1992; Wold et al., 1988, 1992). Pathogenicity-associated islands, which carry many extra-intestinal virulence factors, have been shown to enhance fitness of these strains to survive in the intestinal tract, with the ability to cause extraintestinal infections being a coincidental by-product (Diard et al., 2010). Our unpublished data also indicate that E. coli strains carrying these adhesins bind with almost the same rate to Caco-2 cells (an intestinal epithelial cell line) as they do to the renal cell line.
A-489 (M. Katouli). These findings explain why dominant BPTs in our study carried more pap genes than minor ones.

Zhang et al. (2002) found that E. coli strains carrying P-pili genes in young women (aged 18–39 years) were strongly associated with phylogenetic groups B2 and D. However, group B2 had two distinct subgroups with differing levels of pathogenicity. These researchers suggested that healthy adults are capable of carrying B2 strains but with less virulent subclasses than UTI isolates (Zhang et al., 2002). In our study, B2 was the second major phylogenetic group after group D (except in young adults), suggesting that the B2 strains may be a subset of pathogenic strains that only increase in number and become dominant when there is a major upset of the colonic E. coli leading to UTI. Furthermore, these results indicate that under healthy conditions, and with regard to the E. coli population structure of the gastrointestinal tract, elderly females may be at a greater risk than younger females for UTI from their faecal intestinal flora. Despite this, other factors such as sexual activity increase the likelihood of UTI amongst young women (Hooton et al., 1996). Additionally, healthy males may serve as a reservoir of uropathogens transmitted directly via sexual transmission (Foxman et al., 1997). The low prevalence of uropathogenic virulence factors amongst young women in our study is somewhat contradictory to previous reports of females with UTI which have found that pathogenic urinary strains are often associated with dominant faecal strains (Moreno et al., 2008). These results suggest that a dramatic change may occur in the intestinal E. coli populations of young females before developing UTI. If this hypothesis is correct, then we postulate that a subset of the intestinal E. coli population, probably a minor clone, in young females may find an opportunity to increase in population size, colonize the opening of the urinary tract and become a short-term dominant clone during the course of UTI.

In conclusion, our findings indicate that the E. coli population of healthy young adults has a lower prevalence of VAGs than that of elderly males, and to a lesser extent, elderly females. Despite this, uropathogenic strains are commonly reported as the dominant clones amongst the faecal population in young women with UTI. We postulate that in young females a subset of E. coli populations may increase in size to become a short-term dominant flora during the course of UTI. We also conclude that the presence and dominance of VAGs in E. coli strains in elderly males and females may be a risk factor for developing extraintestinal infections in these groups.
