A novel recombinant human adenovirus (HAdV) species D was isolated from the stool of a pharyngitis patient in Japan and genetic characterization was performed by sequencing variable regions between HAdV types. The nucleotide sequences of the penton base gene and loops 1 and 2 in the hexon gene showed 100% identity with that of the recently identified HAdV-56. Although we observed greatest identity for the entire hexon gene sequence with that of HAdV-56, we noted even greater similarity between the partial nucleotide sequence of the conserved region 4 and that of HAdV-37. Furthermore, the fibre gene and early region 3 sequences were completely identical to that of HAdV-37. These results suggest that the strain is a novel adenovirus related to HAdV-37 and HAdV-56.

INTRODUCTION

Human adenoviruses (HAdVs) are linear double-stranded DNA viruses belonging to the genus Mastadenovirus of the family Adenoviridae. So far, greater than 60 types of HAdV have been identified and grouped into seven species, named HAdV-A through HAdV-G (Jones et al., 2007; Aoki et al., 2008; Ishiko et al., 2008; Walsh et al., 2009, 2010, 2011; Robinson et al., 2011a; Kaneko et al., 2011b; Liu et al., 2011). HAdVs cause a range of illnesses, including pharyngoconjunctival fever (PCF), which is characterized by fever, pharyngitis and conjunctivitis. According to the national surveillance of HAdVs in Japan (Infectious Disease Surveillance Center, 2011), most HAdVs detected in PCF patients belong to the species HAdV-B and HAdV-C, with the most common type being HAdV-3 (HAdV-B) (Fujimoto et al., 2008; Enomoto et al., 2010). However, several types belonging to the species HAdV-D, which are the major cause of keratoconjunctivitis (including types HAdV-8, HAdV-19, HAdV-37, HAdV-53 and HAdV-54) (Ishiko & Aoki, 2009; Kaneko et al., 2011a; Nakamura et al., 2012), were rarely observed in the PCF patients under our surveillance, and instead were mainly detected in keratoconjunctivitis patients.

Recombination, the process by which circulating viruses exchange genes (preferentially within the same species), is important for HAdV evolution (Lukashev et al., 2008). Although serum neutralization tests with type-specific antiserum are traditionally used for HAdV typing, we chose to perform genetic sequence analysis because it proved more efficient for type identification of novel HAdVs (Madisch et al., 2005; Robinson et al., 2011b). The main type-specific epitopes of HAdVs are located in loops 1 and 2 of the hexon protein (ε determinant). The hexon protein is divided into four conserved (C1–C4) and three variable (V1–V3) regions and the variable regions in the hexon loops are type-specific (Ebner et al., 2005). In addition to the hexon gene, genetic analyses revealed that the penton base gene, fibre gene and the early region 3 (E3) are also type-specific (Kaneko et al., 2009; Robinson et al., 2011b). Sequence analysis of these genes has led to the recent identification of novel types of recombinant HAdV-D (Walsh et al., 2009; Robinson et al., 2011a; Kaneko et al., 2011b, 2011c; Liu et al., 2011).

Here, we genetically characterized a recombinant HAdV-D strain using combined nucleotide sequence analysis of the genes mentioned above and compared these sequences with those of other HAdV-D types. The emergence of a novel recombinant HAdV suggests that these recombination events occur relatively frequently, demonstrating that continuous surveillance is important for the identification of novel adenoviruses.

METHODS

Virus strain. A stool sample was obtained from a feverish infant patient with pharyngitis who was treated in July 2011 in Osaka, Japan, during our routine surveillance. For virus isolation, 200 μl of
10% (w/v) stool in Hank’s solution was inoculated into HEp-2 cells with 1 ml of Eagle's minimum essential medium (Sigma) in a 24-well microplate and cultured at 34 °C. Samples (200 µl) were subcultured once a week. Typical cytopathic effect was observed in the second subculture and the isolated strain was named 230272/Osaka/2011.

**DNA sequencing.** Viral DNA extraction and nucleotide sequence analysis were conducted as previously reported (Hiroi et al., 2011). Briefly, PCR was carried out in a 25 µl reaction volume using puRe Taq Ready-To-Go PCR Beads (GE Healthcare) with 1 µl of extracted DNA using specific sets of primers and PCR protocols as described previously, targeting the C4 region (Miura-Ochiai et al., 2007), loops 1 and 2 (Madisch et al., 2005) in the hexon gene and the fibre gene (Xu et al., 2000). To analyse the penton base gene, the entire hexon gene and the E3 region, primers specific for HAdV-37 and HAdV-56 were designed (Table S1, available in JMM Online) and amplification reactions and sequencing primers specific for HAdV-37 were also used to sequence the fibre gene and the E3 region. Nucleotide sequences on both strands of the amplicons were sequenced at a mean of 3-fold coverage. Nucleotide positions are based on the sequence of the deduced hexon protein showed greatest similarity (99.9%) to that of HAdV-56. The results showed the penton base gene was 100% identical to that of HAdV-56, and both the fibre gene and the E3 region were nearly identical to that of HAdV-56 and the greatest identity for the entire hexon gene was noted with that of HAdV-56, the most significant identity for any particular sequence was noted between the partial nucleotide sequence (350 bp) of the C4 region of strain 230272/Osaka/2011 and that of HAdV-37 and HAdV-53 (Fig. 1b–e). Both the fibre gene and the E3 region of strain 230272/Osaka/2011 were located in the same cluster as that of HAdV-37 (Fig. 1f, g). While HAdV-37 and HAdV-53 have strong relationships in several regions including the second half of the hexon protein (Walsh et al., 2009), analysis of the genes displayed no such similarity to HAdV-53, except within the partial nucleotide sequence of the C4 region (Fig. 1a–g). Taken together, these findings suggest that the strain is a novel recombinant type of the species HAdV-D.

The percentage nucleotide similarities of strain 230272/Osaka/2011 genes to those of other HAdV-D types showed that the penton base gene was 100% identical to that of HAdV-56, and both the fibre gene and the E3 region were 100% identical to that of HAdV-37. While the entire hexon gene showed greatest similarity (99.2%) to that of HAdV-56, the loops 1 and 2 of the hexon gene were identical (100%) to those of HAdV-56. The partial nucleotide sequence of the C4 region within the hexon gene showed greatest similarity (98.6%) to that of HAdV-37 and had 98.0% similarity to HAdV-56. Furthermore, the amino acid sequence of the deduced hexon protein showed greatest similarity (99.9%) to that of HAdV-56. The results showed that the e determinant of the novel virus was identical with that of HAdV-56, suggesting that the virus can potentially react with HAdV-15-specific antisera in a manner similar to that previously observed with HAdV-56 (Kaneko et al., 2011b). However, as we were unable to obtain the HAdV-15- and HAdV-56-specific antisera, we could not verify the serological features of this recombinant adenovirus, which led us to conduct our type-classification through nucleotide sequence analysis instead.

We then performed a similarity plot and bootstrap analysis of the hexon gene in order to compare it with that of the HAdV-D types circulating in Japan. The full hexon gene of strain 230272/Osaka/2011 was 2826 bp long, with the first 1520 bp (including both loops 1 and 2) showing 100% similarity to that of HAdV-56 (Fig. 2a). The analysis showed that the nucleotide sequence of the C4 region, downstream of loop 2, had similarity to the other HAdV-D types, in particular the corresponding regions of HAdV-37 and HAdV-56 (Fig. 2a, b). Accordingly, the genes of strain 230272/Osaka/2011 appeared to be related to those of either HAdV-37 or HAdV-56. Although co-infection is required to

induce natural viral recombination, we are unsure of whether such co-infection occurred in the present patient or if he was infected by the novel adenovirus. The strain was isolated from the patient’s stool but, as we did not obtain any other specimens, we were unable to verify infections of the pharynx or conjunctiva. The tropism of the novel adenovirus is unknown; however, our results showed that the fibre and penton base genes, which mediate attachment and internalization of adenoviruses (Smith et al., 2010; Robinson et al., 2011b), were completely identical to those of HAdV-37 and HAdV-56. As both HAdV-37 and HAdV-56 have been shown to cause keratoconjunctivitis (Kaneko et al., 2009, 2011b; Robinson et al., 2011a), this implies that the novel adenovirus may cause not only pharyngitis but also keratoconjunctivitis.

In this study, we reported the isolation and analysis of a novel recombinant HAdV-D strain related to HAdV-37 and HAdV-56. Although the novel adenovirus has not yet been isolated from other patients, and although the recombination events leading to its appearance remain unclear, the virus may have the potential to cause an epidemic. Further genetic analysis of the novel adenovirus is required to clarify its recombination properties.
