SUMMARY

Listeria monocytogenes, in doses of $2.0 \times 10^8$ to $3.0 \times 10^8$ viable organisms, was injected into athymic nude mice, irradiated mice and mice treated with reticuloendothelial system-blocking agents. Viable counts on liver and spleen homogenates were made at intervals after infection. In both nude mice (nu/nu) and normal littermates (nu/+ ) of BALB/c background, the bacteria grew rapidly for 24 h but increased only slowly thereafter, to reach a plateau of about $10^5$ per organ at 72 h. In nu/+ mice, the number of viable bacteria began to decrease after 6 to 9 days, with complete elimination by day 12. In nude mice, the number of Listeria remained at a stable level of approximately $10^5$ per organ during the observation period of 21 days. In lethally irradiated nu/+ mice, bacteria grew progressively and extensively to reach $10^7$ per spleen and $10^9$ per liver by 72 h. Bacterial growth during the first 72 h was markedly enhanced by treatment with carbon particles, dextran sulphate 500 or silica. These enhancing effects were also observed in nude mice and in AKR, C3H/He and C57BL/6 animals. We conclude that both non-immune phagocytes and T cell-dependent mechanisms contribute to the resistance of mice to Listeria infection.

INTRODUCTION

Protection against Listeria monocytogenes has been reported to depend primarily on macrophages which are activated specifically or non-specifically by sensitized lymphocytes. Activated macrophages with antilisterial activity were generated by immunization not only with L. monocytogenes, but also with Brucella (Mackaness, 1964), Mycobacterium bovis (BCG) (Mackaness, 1964) or Toxoplasma (Krahenbuhl & Remington, 1971). Furthermore, macrophages activated by listeria infection also inhibit intracellular growth of Salmonella typhimurium (Blanden, Mackaness & Collins, 1966) and Candida albicans (Marra & Balish, 1974). Thymus-derived (T) lymphocytes are required for activation of macrophages both in vivo and in vitro (Lane & Unanue, 1972; North, 1973a; Cole, 1975). However, protection against these infections depends not only on T cell-mediated immunity, but also on the normal antimicrobial activity of phagocytes, including non-immune macrophages and neutrophils. Most of the investigations cited above were performed under conditions where both innate and induced immunity mechanisms might operate simultaneously. This study was designed to analyse the contribution of each of these elements to the elimination of L. monocytogenes. Thus bacterial growth has been monitored in athymic nude mice and in mice treated with irradiation and with reticuloendothelial system-blocking agents.
METHODS

Animals. Athymic nude mice (nu/nu) of BALB/c background and their normal littermates (nu/+ ) were obtained from the Central Laboratory for Experimental Animals, Tokyo. They were raised in specific pathogen-free conditions and maintained in our laboratory in clean but not germ-free surroundings. Pellets, drinking water and bedding were sterilized in an autoclave and cages were covered with filter caps to minimize microbial contamination. Inbred mice of C3H/He, AKR and C57BL/6 strains were obtained from the Breeding Unit of Kyushu University, School of Medicine. They were raised and maintained in conventional conditions. Eight-week-old mice were used for experiments.

Micro-organism. Listeria monocytogenes (EGD) was kindly donated by Dr Ishibashi, Research Institute for Diseases of the Chest, Kyushu University, School of Medicine. The bacteria were maintained by serial passage in outbred CF, mice. Fresh isolates were obtained from infected spleens, grown once on Tryptic Soy Agar medium (Difco) and used for infection.

Determination of bacterial growth in organs. Mice were inoculated intravenously with $2 \times 10^3$ to $3 \times 10^3$ viable bacteria in saline. At various times after infection, they were bled by cutting the femoral artery, and the spleen and liver were removed. Individual organs were homogenized separately in 10 ml phosphate-buffered saline (PBS) with Teflon homogenizers. The homogenized suspensions were diluted serially 10-fold with PBS and 0.1 ml of each dilution was spread on Tryptic Soy Agar. Three plates were prepared for each dilution of each specimen. Colonies were counted after incubation for 20 h at 37°C.

X-irradiation. Mice were exposed to 900 R of whole body X-irradiation and infected 3 days later. The radiation was delivered from a Shimadzu 250 kV machine operating at 200 kV with 1 mm Cu and 1 mm Al filtration at 100 cm from the target focus.

Blockade of the reticuloendothelial system. Carbon was administered according to Fisher (1966), but with minor modifications. Carbon particles (C11/1431a, Günther, Wagner) were suspended at 25 mg ml$^{-1}$ in saline containing 1% gelatin, and 0.2 ml was injected intravenously on days -1 and 0, and intraperitoneally on day 1 (with respect to infection). Dextran sulphate 500 (DS-500, mol. wt 500000; Pharmacia) was dissolved in 0.15 m-NaCl at 5 mg ml$^{-1}$ and a dose of 50 mg kg$^{-1}$ was given in each injection, according to Hahn (1974). Doses were administered once on day -1 or twice on days -1 and 0. Silica (2 pm average diam.) was suspended at 50 mg ml$^{-1}$ in saline according to Zisman, Hirsch & Allison (1970), and 1 ml was injected intraperitoneally three times on days -1, 0 and 1. All of the above mice were inoculated with L. monocytogenes on day 0.

RESULTS

Growth of bacteria in nude mice

A suspension containing $2.6 \times 10^3$ L. monocytogenes was injected intravenously into nu/nu and nu/+ mice on day 0 and live bacteria in the spleen and liver were counted up to 21 days later. Three animals were taken from each group at each time. Numbers of live bacteria in the liver and spleen were slightly higher in nu/+ than in nu/nu mice on day 3 (Fig. 1). However, they had begun to disappear by day 6 and day 9, respectively, from the spleen and liver of nu/+ mice and were eliminated completely by day 12. On the other hand, approximately $10^6$ live bacteria were detected in both organs of nu/nu mice during the whole observation period of 21 days.
Protection against listerial infection

Early growth of bacteria in irradiated mice

A suspension containing 2.0 x 10^9 *L. monocytogenes* was injected intravenously into nu/nu, nu/+ and irradiated nu/+ mice on day 0. Live bacteria in the spleens and livers from three mice of each group were counted 1, 24, 48 and 72 h later. In the spleens from mice of all three groups, few live bacteria were detected 1 h after inoculation (Fig. 2a), but numbers increased rapidly to reach over 10^4 per spleen by 24 h. Thereafter numbers of bacteria increased only slightly in nu/nu and nu/+ mice, while the count in irradiated nu/+ mice increased progressively to reach over 10^7 by 72 h. Similar patterns of bacterial growth were observed in the
Fig. 3. Growth of *L. monocytogenes* after an intravenous inoculation of $3 \times 10^3$ live bacteria into normal (○) and DS-500-treated (●) C3H/He mice. Each point represents an average of five animals.

livers from mice of these groups, although the total numbers of live bacteria per organ were higher than in the corresponding spleens (Fig. 2b).

**Effect of reticuloendothelial blockade**

To find out the effect of reticuloendothelial blockade, DS-500 was injected intraperitoneally into C3H/He mice on day −1 and $3 \times 10^3$ *L. monocytogenes* was injected intravenously on day 0. Live bacteria were counted in the spleen and liver 2, 3 and 4 days later. Pretreatment with DS-500 enhanced growth in the spleen but this was only detected on day 3 (Fig. 3a). Enhancement of bacterial growth in the liver was most prominent on day 3, although present to a lesser extent on days 2 and 4 (Fig. 3b). To explore this further, the effects of blocking agents administered 3 days after infection were examined.

A suspension containing $3 \times 10^3$ *L. monocytogenes* was injected intravenously into four groups of nu/nu and nu/+ mice and bacteria in the spleen and liver were counted 3 days...
Protection against listerial infection

Fig. 5. Growth of *L. monocytogenes* at 3 days after an intravenous inoculation of $3 \times 10^3$ live bacteria into AKR mice which had been treated with carbon, DS-500 or silica. Open and closed columns represent the numbers of bacteria in the spleen and liver, respectively. Each column represents an average of five animals.

later. Each group consisted of five animals. Bacterial growth in both nu/nu and nu/+ mice was markedly enhanced by injection of carbon or DS-500 (Fig. 4). The numbers of bacteria in mice treated with such agents reached $10^8$ to $10^9$ in the spleen and $10^9$ to $10^10$ in the liver, while in non-treated nu/nu and nu/+ mice there were less than $10^5$ in both organs. Bacterial growth was also enhanced by treatment with silica, although to a lesser extent than by treatment with the other two agents. No difference in the degree of enhancement was detected between nu/nu and nu/+ mice.

The effects of the blocking agents on bacterial growth were also investigated in conventional AKR, C3H/He and C57BL/6 mice. When no blocking agent was given, the number of live bacteria per organ was greatest in AKR, smallest in C57BL/6 and intermediate in C3H/He mice. Bacterial growth in the spleen and liver of AKR mice was enhanced markedly by carbon and DS-500 (Fig. 5). Treatment with silica slightly enhanced bacterial growth in the liver but not in the spleen. Similar patterns of enhanced bacterial growth were observed in C3H/He and C57BL/6 mice, although the degree of enhancement varied slightly among the different combinations of host strains and blocking agents.

**DISCUSSION**

Protection against some kinds of micro-organisms depends on T cell-mediated immunity. Susceptibilities to such micro-organisms have been thought to increase in hosts with depressed functions of T lymphocytes. Increased susceptibilities of nude mice to experimental infections with *L. monocytogenes* (Emmerling, Finger & Bockemühl, 1975), *M. bovis* (BCG) (Sher *et al.*, 1975; Takeya *et al.*, 1977), *Babesia microti* and *Plasmodium berghei yoelii* (Clark & Allison, 1974) have been reported. According to Emmerling *et al.* (1975), viable organisms of *L. monocytogenes* were eliminated from the spleen of normal littermates in the typical course of an experimental infection, but were retained persistently in nude mice from an initial stage to a late stage of infection. We have confirmed their results (see Fig. 6). According to North (1973b), antilisteria immunity was not impaired in mice that had been thymectomized, irradiated and reconstituted with bone marrow cells (THXB mice), but their capacity to develop antituberculous immunity was greatly reduced. This observation is explained in terms of a residual T cell population in THXB mice which is large enough to
generate antilisteria, but not antituberculous immunity. Thus, nude mice may have more depressed functions of T lymphocytes than THXB mice. Studies of nude mice may provide a new method for analysing the contribution of T cell-mediated immunity to the protection against at least some micro-organisms, although θ-positive cells still exist in nude mice (Loor & Roelants, 1974) and they increase in number in nude mice infected with mouse hepatitis virus (Scheid, Goldstein & Boyse, 1975).

We expected to find a fulminating course of infection with \( L. \) monocytogenes in nude mice, since resistance to such organisms was generally considered to depend largely on T cell-mediated immunity. However, nude mice showed a persistent form of infection rather than a fulminating course. The contribution of mechanisms other than T cell-mediated immunity has to be taken into account to understand the resistance to \( L. \) monocytogenes as a whole. Contribution of cells other than T lymphocytes was suggested by McGregor, Hahn & Mackaness (1973). They found that thymectomized, irradiated rats rapidly regained the capacity to defend themselves from a primary infection with \( L. \) monocytogenes, when given syngeneic bone marrow cells. Such a resistance could be transferred with thoracic duct cells or peritoneal exudate cells, although the efficiency was not so good. In their system, the contribution of T lymphocytes to the recovery of the resistance may be small, if any.

Possible explanations of the resistance described above are protection by phagocytes, including non-immune macrophages and neutrophils, and protection by humoral immunity. A fulminating bacterial growth at an early stage of infection may be suppressed by the mechanism(s) which is present in nude mice and sensitive to lethal irradiation. There is some doubt about the radiosensitivity of fixed macrophages. The capacity to engulf carbon particles has been reported to be highly radioresistant (see Nelson, 1969). However, the capacity to digest engulfed chicken erythrocytes or Candida cells was reported to be radiosensitive (Donaldson et al., 1956). The enhanced bacterial growth within 72 h after infection in lethally irradiated mice may be ascribed to the depletion of the capacity of macrophages to digest bacterial cells, although such an experiment is not conclusive.

DS-500, a blocking agent of the reticuloendothelial system, enhanced bacterial growth within 3 days after infection with Listeria, as reported by Hahn (1974). Carbon particles enhanced bacterial growth to almost the same extent as DS-500. Bacterial growth was also enhanced by silica, although this was less effective than DS-500 or carbon particles. Enhancement was detected in all nu/nu, nu/+ AKR, C57BL/6 and C3H/He mice and may be ascribed to the depletion of non-immune phagocytes. It is not due to the suppression of immune macrophages which may be generated in the presence of antigen-specific sensitized lymphocytes.

Three days after infection, the numbers of live bacteria in the spleen and liver were slightly lower in nude mice than in normal littermates, an observation that may be attributed to a higher level of macrophage activation in nude mice. At least two explanations could account for this phenomenon, as suggested by Meltzer (1976). First, macrophage functions may be augmented in the presence of a deficient homeostatic T cell effect. Secondly, macrophages may be activated more readily in nude mice by subclinical infection and by interactions with natural bacterial flora and bacterial by-products. The latter explanation is more likely since Meltzer did not detect augmented macrophage activation in germ-free nude mice.

Thus, a defence mechanism by non-immune phagocytes appears to play an important role in resistance to \( L. \) monocytogenes, especially at an early stage after infection. Fulminating bacterial growth may be suppressed by such a mechanism before immunological mechanisms are raised several days after infection. Activated immune macrophages appear to be required for complete elimination of bacteria at a late stage of infection.
Protection against listerial infection
