Biosynthesis of Thiamin in Bacillus subtilis. 
Isolation of Mutants Accumulating 4-Amino-5-hydroxymethyl-
2-methylpyrimidine Phosphate

(Received 16 May 1977; revised 16 July 1977)

Thiamin-deficient mutants of Bacillus subtilis were characterized by their growth responses to the pyrimidine and thiazole moieties of the vitamin molecule and by cross-feeding tests. All mutants growing on the thiazole moiety and all mutants with an absolute requirement for thiamin fed all those growing on the pyrimidine moiety. No other cross-feeding effects were observed. From the culture fluid of a mutant growing on the thiazole moiety, two compounds were isolated which supported growth of mutants requiring the pyrimidine moiety. These compounds were identified by chromatographic, bioautographic and spectrophotometric procedures as 4-amino-5-hydroxymethyl-2-methylpyrimidine and its monophosphate derivative.

INTRODUCTION

The enzymic formation of thiamin from 4-amino-5-hydroxymethyl-2-methylpyrimidine (which, throughout this paper, will be termed hydroxymethylpyrimidine) and 5-(β-hydroxyethyl)-4-methylthiazole (=thiazole) has been studied in considerable detail in various microorganisms. Hydroxymethylpyrimidine is converted to the pyrophosphate by the subsequent action of two phosphokinases (Camiener & Brown, 1960a, b). Thiazole is converted to the monophosphate. The two phosphoric acid esters are condensed with formation of thiamin monophosphate (Leder, 1959). Thiamin monophosphate is converted to the pyrophosphate by direct phosphorylation in Escherichia coli and in Micrococcus sp. (Nishino, Iwashima & Nose, 1971; Sanemori, Egi & Kawasaki, 1976). In yeast, however, thiamin monophosphate is hydrolysed to free thiamin which is subsequently converted to the pyrophosphate by thiamin pyrophosphokinase (Camiener & Brown, 1959).

The basic pathways leading to the pyrimidine and thiazole moieties of the vitamin molecule are incompletely understood. Isotope incorporation studies with a variety of basic metabolites in various organisms yielded conflicting results. The extensive literature has been reviewed by Brown (1972).

The frequent occurrence of pleiotropic Ath- mutants requiring both adenine and thiamin led Newell & Tucker (1968a, b) to the concept of a basic common pathway for the biosynthesis of these metabolites. The thiamin requirement of an Ath- mutant of Salmonella typhimurium was satisfied by the purine precursor, 4-aminomidazole riboside phosphate. Newell & Tucker proposed that this compound is a precursor of the pyrimidine moiety of thiamin.

Nakayama (1956) found that mutants of E. coli deficient in the pyrimidine moiety of thiamin can grow on hydroxymethylpyrimidine and also on its 5-formyl and 5-aminomethyl analogues. All three compounds and the 5-methoxymethyl analogue were isolated from the
culture fluid of a thiamin-deficient mutant of *Neurospora crassa* (Diorio & Lewin, 1968a, b). Wei & Lewin (1970, 1971) described the conversion of 4-amino-5-aminomethyl-2-methylpyrimidine (=aminomethylpyrimidine) and 4-amino-5-formyl-2-methylpyrimidine (=formylpyrimidine) to hydroxymethylpyrimidine by cell extracts of *Saccharomyces cerevisiae*.

Two unlinked thi genes have been mapped on the chromosome of *Bacillus subtilis* (Young & Wilson, 1975), but the mutants have not been characterized biochemically. The present paper describes the isolation and biochemical characterization of thiamin-deficient mutants of *B. subtilis*. A mutant requiring thiazole for growth was found to excrete hydroxy-methylpyrimidine phosphate.

**METHODS**

**Chemicals.** Hydroxyethylpyrimidine, aminomethylpyrimidine and thiazole were kindly provided by Hoffmann-La Roche, Basle, Switzerland. 4-Amino-5-chloromethyl-2-methylpyrimidine (=chloromethylpyrimidine) was a gift from BASF, Ludwigshafen, W. Germany. Thiamin, thiamin pyrophosphate and charcoal (1×5 mm) were purchased from Merck; Dowex 1-X8 and Dowex 50W-X8 from Serva, Malsch, W. Germany; thiamin monophosphate from Fluka, Buchs, Switzerland; AG 1-X8 from Biorad; and alkaline phosphatase from Boehringer.

5-(β-Hydroxyethyl)-4-methylthiazole 2'-phosphate (=thiazole phosphate) was prepared according to Lohmann & Schuster (1937). 4-Amino-5-hydroxymethyl-2-methylpyrimidine phosphate (=hydroxymethylpyrimidine phosphate) was prepared from chloromethylpyrimidine according to Lewin & Brown (1963). The compound was purified by chromatography on a column of Dowex 1-X8 (formate form, 2×20 cm, elution with a gradient of 0 to 0.4 M-ammonium formate).

**Media.** Complete medium contained (g per l deionized water): nutrient broth (Difco), 8.0; yeast extract (Oxoid), 3.0; glucose, 3.0. The minimal medium was Spizizen's medium (Spizizen, 1958) supplemented with l-tryptophan (50 mg l⁻¹). The medium was further supplemented as required in each experiment.

**Strains.** *Bacillus subtilis* 168m, trpC₂, was kindly provided by Dr C. Anagnostopoulos, Gif sur Yvette. Thiamin-deficient mutants are described in Results.

**Isolation of mutants.** *Bacillus subtilis* 168m was harvested in the early exponential phase of growth and suspended in citrate/phosphate buffer pH 7. N-Methyl-N'-nitro-N-nitrosoguanidine was added to a final concentration of 20 mg l⁻¹ and the suspension was incubated at 37 °C for 40 min. The bacteria were then pelleted, washed, and resuspended in complete medium supplemented with adenine (50 mg l⁻¹) and thiamin pyrophosphate (1 mg l⁻¹). The suspension was incubated overnight with shaking. Bacteria were plated on complete medium supplemented with adenine (50 mg l⁻¹). Colonies were replicated on minimal medium and on minimal medium supplemented with thiamin (1 mg l⁻¹), thiamin pyrophosphate (1 mg l⁻¹) and adenine (50 mg l⁻¹).

**Growth tests.** Approximately 10⁷ washed bacteria from an overnight culture were inoculated into flasks containing 20 ml minimal medium supplemented as required, and incubated at 37 °C with shaking. Turbidity (623 nm) was measured after 20 h.

**Cross-feeding tests.** Method A. Approximately 10⁸ washed bacteria from an overnight culture were suspended in 20 ml minimal agar and plated. Suspensions of tester strains (10⁸ bacteria ml⁻¹) were then streaked on the plates. Growth of streaks was examined after 2 days.

Method B. Feeder mutants were grown in complete medium, washed, and resuspended in minimal medium. The suspensions were incubated overnight and then the culture fluid was separated and filter-sterilized. Portions were added to flasks containing 20 ml minimal medium. The flasks were heat-sterilized and inoculated with 10⁷ washed bacteria of the tester strains. Turbidity was monitored after 20 h incubation.

**Bioautography.** Method A. Paper chromatograms were placed on minimal agar plates containing the tester strain (10⁸ bacteria ml⁻¹). After 90 min, the chromatograms were removed, and the plates were incubated overnight.

Method B. Chromatograms were cut, and the strips were soaked in 20 ml minimal medium for 2 h. The medium was sterilized and inoculated with the tester strain as described under growth tests.

**Reversion.** Approximately 10⁸ bacteria were plated on minimal medium supplemented as required. Colonies were examined after 2 days.

**Fermentation.** Mutant T57 was grown in 10 l minimal medium supplemented with thiamin (30 μg l⁻¹) at 37 °C with stirring (300 rev. min⁻¹) and aeration (180 l h⁻¹). Bacteria were harvested after 24 h and resuspended in 10 l of thiamin-free minimal medium. The suspension was incubated for 24 h as described above and the bacteria were removed by centrifugation.

**RESULTS**

Mutants of *Bacillus subtilis* were obtained after treatment of strain 168M with *N*-methyl-*N*-nitro-*N*-nitrosoguanidine in four independent mutation experiments. In a total of 53 mutants growing on thiamin and 224 mutants growing on adenine, no Ath⁻ mutants, with simultaneous requirement for both thiamin and adenine, were obtained. Similarly, no mutants with a specific requirement for thiamin pyrophosphate were found.

The thiamin-deficient mutants were further characterized by their growth responses to hydroxymethylpyrimidine and thiazole (Table 1). All mutants growing on hydroxymethylpyrimidine were also able to grow on the 5-aminomethyl and the 5-chloromethyl analogues and on hydroxymethylpyrimidine phosphate. Twenty-one mutants were unable to grow on hydroxymethylpyrimidine, thiazole or the corresponding phosphoric acid esters.

Three mutants required the simultaneous presence of hydroxymethylpyrimidine and thiazole for growth. These mutants were analysed by reversion tests. No spontaneous prototrophic revertants were obtained from any of them. However, all three mutants spontaneously segregated revertants growing on hydroxymethylpyrimidine in the absence of thiazole at a frequency of $10^{-8}$. Revertants growing on thiazole in the absence of hydroxymethylpyrimidine were also segregated at a similar frequency. We conclude that the mutants had acquired genetic defects in two different thiamin genes.

Three mutants could grow on either hydroxymethylpyrimidine or thiazole. However, further analysis showed that they could also grow on various amino acids (glycine, serine, phenylalanine, threonine, isoleucine, methionine) in the absence of any specific thiamin precursor. The basis for this behaviour is not understood.

The single-step mutants with a clearcut requirement for thiamin or one of the supposed precursors mentioned were studied by cross-feeding tests in several combinations (Table 2). All mutants with an absolute requirement for thiamin were able to feed those with a requirement for hydroxymethylpyrimidine. Similarly, all thiazole-requiring mutants fed the hydroxymethylpyrimidine-requiring mutants. No other cross-feeding phenomena were observed. In particular, the thiazole-deficient mutants did not respond to metabolic products from any strain studied. From these data, we tentatively concluded that the thiazole-deficient mutants and those with an absolute requirement for thiamin produce and excrete one or more compounds capable of replacing the pyrimidine moiety of thiamin. Subsequent studies were concerned with the isolation and identification of these compounds.
The thiazole-requiring mutant T57 was grown in minimal medium supplemented with thiamin. The bacteria were harvested, resuspended in thiamin-free medium, and incubated overnight. Samples were taken at the beginning and at the end of the incubation period. These suspensions were sterilized and analysed for growth-promoting material by bioassay with the hydroxymethylpyrimidine-deficient mutant T6. We found that the amount of such material increased by a factor of 5 during incubation of mutant T57 in minimal medium, thus indicating its de novo formation. The amount of growth-promoting material produced corresponded to 0.15 mg thiamin equivalents per 1 culture medium.

Accumulation experiments with mutant T57 were performed in 10 l batches as described in Methods. The cell-free culture fluid was passed through a column of charcoal (8 x 12 cm). The column was washed with water and the growth-promoting material was eluted with ethanol/water (1:1, v/v; 2 l). The elution was followed by bioassay with mutant T6. The recovery of growth-promoting material was 90%. The eluate was taken to dryness under reduced pressure and the residue was dissolved in 3 ml deionized water. The solution was placed on a column of Dowex 50W-X8 (H⁺ form, 1.7 x 67 cm) which was developed with a linear gradient of 0 to 4 M-HCl (total volume, 2 l). Elution of thiamin metabolites was followed by bioassay. The elution pattern is shown in Fig. 1. Two different fractions stimulating growth of the hydroxymethylpyrimidine-deficient mutant T6 were eluted by 1.2 and 2.3 M-HCl. These fractions were taken to dryness under reduced pressure.

The material eluted by 2.3 M-HCl (compound I) was placed on a column of AG 1-X8 (formate form, 2 x 20 cm). The column was developed with a linear gradient of 0 to 0.4 M-ammonium formate (total volume, 500 ml). The elution was followed by bioassay with mutant T6 (Fig. 2). A single peak of growth-promoting material was observed in the eluate, at 0.1 M-ammonium formate. The ultraviolet spectrum of compound I showed the characteristic features of a simple pyrimidine derivative (λ_max in 0.1 M-HCl, 245 nm; λ_max in 0.1 M-NaOH, 271 and 233 nm). By chromatographic comparison with various pyrimidine derivatives, compound I was identified as hydroxymethylpyrimidine. Compound I showed the same elution patterns as an authentic sample of hydroxymethylpyrimidine on columns of Dowex 50W-X8 and AG 1-X8, respectively (experimental conditions as described above). In addition, both compounds migrated the same distance on paper chromatograms (Table 3).
Fig. 2. Chromatography of compound 1 on a column of AG 1-X8 (formate form, 2 x 20 cm, elution with a gradient of ammonium formate). Bioautography (E<sub>422</sub>), ---; concentration of eluant, ---.

Further purification of compound 2 (eluted from Dowex 50W-X8 by 1·2 M-HCl, see above) was performed by chromatography on a column of AG 1-X8 under the experimental conditions described above. Fractions with growth-promoting activity were eluted by 0·1 and 0·35 m-ammonium formate (Fig. 3). When the material eluted by 0·35 m-ammonium formate was subsequently rechromatographed under the same conditions, the same pattern of two growth-promoting fractions eluted by 0·1 and 0·35 m-ammonium formate was again observed. This indicates that compound 2 decomposes slowly under these conditions with formation of the material eluted by 0·1 m-ammonium formate. The identity of the latter compound with hydroxymethylpyrimidine was shown by the procedures described above (Table 3). It follows that compound 2 is a derivative of hydroxymethylpyrimidine. The conversion of compound 2 to hydroxymethylpyrimidine is greatly accelerated by alkaline phosphatase. The hypothesis that compound 2 is the phosphoric acid ester of hydroxymethylpyrimidine was confirmed by comparison with an authentic sample of hydroxymethylpyrimidine phosphate. The compounds were identical with respect to (i) chromatography on columns of Dowex 50W-X8 and AG 1-X8, (ii) paper chromatography (Table 3), (iii) hydrolysis by alkaline phosphatase, and (iv) ultraviolet spectra.
Table 3. Paper chromatography of accumulation products of B. subtilis mutant 157 and authentic compounds

Compounds were spotted on Macherey & Nagel paper MN 263 and developed by ascending chromatography. Spots were detected by bioautography as described in Methods. Solvent systems: 1, 2-propanol/1 M-HCl (17:8, v/v); 2, 2-propanol/acetic acid/water (170:41:39, v/v).

DISCUSSION

A total of 53 thiamin-deficient mutants of B. subtilis obtained in four mutation experiments have been characterized by feeding and accumulation tests. The results suggest the existence of considerable differences of mutant types among different microbial species.

Mutants with a double requirement for thiamin and purines (Ath-) have been isolated from S. typhimurium (Yura, 1956) and E. coli (Stouthamer, de Haan & Nijkamp, 1965). In the latter species, two ath loci were assigned to early steps in the biosynthesis of purines. No Ath- mutants were found in studies on Sacch. cerevisiae (Muller-Falcke, 1974). In the present work, attempts to isolate mutants with a double requirement for thiamin and adenine were unsuccessful although 224 adenine-deficient mutants and 53 thiamin-deficient mutants were isolated. Since the mutants were derived from a limited number of mutagenized cultures, the possibility remains that several isolates were descendants of the same original mutant. With this qualification, the material represents a minimum of 22 independent Thi- mutants. On this basis, we suggest tentatively that either Ath- mutants may not exist in B. subtilis or that they may have additional metabolic defects which interfere with their detection.

Mutants with a double requirement for the pyrimidine and thiazole moieties occur frequently in Sacch. cerevisiae and in N. crassa. In Sacch. cerevisiae, this phenotype can be produced by mutation in one of several unlinked genes (Muller-Falcke, 1974). In the present study, all mutants of B. subtilis with a double requirement for the pyrimidine and the thiazole moieties were shown to be double mutants.

The cross-feeding experiments with the B. subtilis mutants showed a surprisingly simple pattern. Only one group of feeding strains comprising all mutants with an absolute requirement for thiamin and all mutants growing on thiazole was found. The feeder mutants were able to feed all mutants requiring the pyrimidine moiety. This suggested that the feeding mutants produce one or more compounds of the pyrimidine pathway which cannot be metabolized further due to the genetic defect. This was confirmed by the isolation, in pure form, of two compounds with growth-promoting activity from the culture fluid of a thiazole-deficient mutant. The de novo formation of these metabolites was ascertained by quantitative bioassays. The compounds were subsequently identified as hydroxymethylpyrimidine and its monophosphate derivative. The isolation of hydroxymethylpyrimidine phosphate from a microbial culture has not been reported previously, although the enzymic formation of the compound by a yeast enzyme is known (Camiener & Brown, 1960a). No other growth-promoting factors were found. In particular, the accumulation of aminomethylpyrimidine
was ruled out by a reconstruction experiment using the authentic compound. It is possible that the isolated hydroxymethylpyrimidine originates from the degradation of the monophosphate since we have found that the latter compound is rather unstable under our experimental conditions.

The pyrimidine-deficient mutants could not be subdivided by cross-feeding experiments. In particular, all of them were able to utilize chloromethylpyrimidine and aminomethylpyrimidine, i.e. no mutants had an absolute requirement for hydroxymethylpyrimidine.

Surprisingly, none of the thiazole-deficient mutants could be fed by any of the other mutants. This may indicate that thiazole is an intermediate in a salvage pathway rather than in the de novo synthesis of the vitamin (Harris, 1955, 1956). To the best of our knowledge, thiazole compounds have not been isolated from thiamin-deficient mutants.

This work was supported by the Deutsche Forschungsgemeinschaft. Professor F. Lingens kindly provided the facilities and support of his institute. The technical assistance of E. Gerbershagen is gratefully acknowledged.
