(Received 31 July 1978)

The phosphorus content of phosphate-limited Saccharomyces cerevisiae was only 71% of that of non-limited yeast. Walls prepared from phosphate-limited cells contained slightly less phosphorus than control walls. No evidence was obtained for the presence in these walls of uronic acid or succinyl residues. The carbohydrate content of walls of phosphate-limited yeast was less than that of non-limited walls, and this was reflected in a decreased glucan content. There was only a slight decrease in glucosamine content while the protein content increased. The major change in the lipid composition of phosphate-limited yeast was a decrease in both sterol esters and triacylglycerols. There was a decrease in total lipid content, but increased production of phosphatidylyethanolamine and phosphatidylcholine. The phosphatidylserine content was decreased. These results suggest that there are fewer intracellular low-density vesicles in phosphate-limited yeast.

INTRODUCTION

Phosphate limitation of growth induces substantial changes both in the cell-wall composition and in the lipid composition of certain bacteria. These include replacement of wall teichoic acid by a phosphorus-free anionic polymer, teichuronic acid (Ellwood & Tempest, 1972), and partial replacement of acidic phospholipids by acidic glycolipids (Minnikin et al., 1974). By contrast, very little is known of the effects of this growth constraint on the composition of the yeast Saccharomyces cerevisiae. The present paper reports an analysis of the changes in cell-wall and lipid composition resulting from growth of S. cerevisiae NCYC 366 under phosphate limitation. This strain was chosen because its lipid composition, under a variety of other growth conditions, has been well documented (Hunter & Rose, 1972).

METHODS

Organism and growth media. Saccharomyces cerevisiae NCYC 366 was grown in the defined medium of Rose & Nickerson (1956) supplemented with L-asparagine (1 g l⁻¹). For phosphate-limited cultures, the concentration of KH₂PO₄ was decreased from 3 g l⁻¹ to 81.6 mg l⁻¹. Stock cultures were maintained at 4 °C on slopes of complete medium.

Experimental cultures. Non-phosphate-limited (control) cells were grown in batches at 30 °C in a 15 l fermenter (LH Engineering Co., Stoke Poges, Bucks.). An overnight culture (0.5 l) was used to inoculate 14.5 l medium. Mixing was accomplished by an impeller operating at 400 rev. min⁻¹ and sterile air was sparged through the culture at 10 l min⁻¹. Cells were harvested in the mid-exponential phase of growth (A₅₄₀ = 1.0) when the growth rate was 0.34 h⁻¹.

Phosphate-limited cells were grown continuously at 30 °C in a 2 l chemostat (Hunter & Rose, 1972). The dilution rate was 0.23 h⁻¹. At regular intervals samples were removed aseptically through a drain point in

the floor of the vessel and used to check the purity, absorbance ($A_{650}$) and pH of the culture. The concentration of orthophosphate (as phosphorus) in cell-free filtrates was also monitored. Steady-state cells were harvested either by draining the vessel to about 10% (v/v) of the initial volume or by recovery from the chilled overflow receiver at short, regular intervals. Cells from both batch and continuous cultures were washed twice in 0.85% (w/v) NaCl and once in distilled water at 4 °C. They were then either stored at -20 °C or freeze-dried and stored in vacuo over silica gel.

Preparation of walls. Cells were suspended in cold water (approximately 10 g wet wt cells in 10 ml water) and shaken with no. 10 Ballottini beads (10 g) for 75 to 90 s at 4000 rev. min⁻¹ in a Braun MSK homogenizer (B. Braun, Melsungen, West Germany). The temperature was maintained at 0 to 4 °C throughout the disruption. Beads were removed by filtration through a sintered glass filter (porosity grade 0) and the filtrate was centrifuged at 750g for 20 min. The wall pellet was washed 10 times in 0-1 m-Tris/HCl buffer (pH 7.2) and then four times in distilled water; the temperature remained below 4 °C throughout. Absence of intact yeast from the wall preparations was established by phase-contrast microscopy. Walls were freeze-dried and stored in vacuo over silica gel.

Treatment of walls with β-glucanase and α-mannosidase. A suspension of walls (12 mg) in 6 ml 0-05 m-sodium citrate buffer (pH 5-0), containing 10 mm-MgCl₂ and 10 mm-ZnSO₄, was supplemented with 3.75 units of a-mannosidase and 50 units of β-glucanase solution (10 mg ml⁻¹) and incubated at 30 °C for 35 min. Portions (0-1 ml) removed at time zero and after 35 min were diluted to 3 ml with distilled water and their absorbance at 650 nm was measured against a distilled water blank.

Acid hydrolysis of enzymically treated wall suspensions. Portions of wall suspension, equivalent to 3-6 mg untreated wall, were hydrolysed in 1 m-HCl at 105 °C in vacuo for 2 to 4 h. Following neutralization with 0-5 m-KOH, the hydrolysates were centrifuged at 1100g for 5 min to remove insoluble material and stored at -20 °C.

Analysis of walls and wall hydrolysates. Prior to analysis all wall suspensions were homogenized for 1 min in a sonic water bath. Total carbohydrate was determined by the phenol-sulphuric acid method (Dubois et al., 1956). Glucose and mannose were determined enzymically, glucose by the glucose oxidase reagent and mannose by the method of Gawehn (1974). Phosphorus was estimated as described by Letters (1964). Protein (as bovine serum albumin) was determined by the method of Lowry et al. (1951); prior to analysis wall samples were digested in dilute alkali [2% (w/v) Na₂CO₃ in 0-1 m-NaOH] in glass-stoppered tubes for 30 min in a steam bath. Glucosamine was assayed by the method of Rondle et al. (1950); aniline-diphenylamine for neutral sugars and uronic acids (Bailey, 1969) and then four times in distilled water; the temperature remained below 4 °C throughout. Absence of intact yeast from the wall preparations was established by phase-contrast microscopy. Walls were freeze-dried and stored in vacuo over silica gel.

Paper chromatography. Descending chromatography was carried out on Whatman no. 1 paper in the following solvent systems: A, butan-1-ol/pyridine/water (6:4:3, by vol.); B, ethyl acetate/pyridine/acetic acid/water (5:5:1:3, by vol.). Hydrolysis products were identified by co-chromatography with authentic standards and the use of the following specific spray and dip reagents: alkaline silver nitrate for sugars (Trevelyan et al., 1950); aniline-diphenylamine for neutral sugars and uronic acids (Bailey, 1969); bromophenol blue for non-volatile acids (Kennedy & Barker, 1951); bromocresol green-bromophenol blue-permanganate for non-volatile acids (Pásková & Munk, 1960).

Lipid analyses. Lipids were extracted from cells, and determinations were made of total lipid, total phospholipid, individual phospholipids and acylglycerols as described by Hunter & Rose (1972) and Hossack & Rose (1976). Free sterols were assayed by a modification of the method of Jatzkewitz & Mehl (1960). Samples of sterol solution, containing up to 0-1 mg sterol, were evaporated to dryness using a stream of nitrogen. Then 2 ml sulphuric acid (sp.gr. 1-84)/glacial acetic acid (1:1, v/v) were added to each tube, and the tubes were placed in a water bath at 90 °C for 15 min. After cooling, the absorbance at 390 nm was measured against a reagent blank; ergosterol was used as a standard. Sterol esters were assayed by determining the amount of free sterol liberated upon saponification (Hunter & Rose, 1972). Chemicals. Basidiomycete QM806 β-glucanase was kindly provided by Professor A. H. Rose (University of Bath). α-Mannosidase and the glucose oxidase blood sugar kit were obtained from Boehringer; silica gel was from Merck. All other biochemicals were purchased from Sigma. Solvents and other chemicals were of analytical grade where available and were obtained from BDH. All solvents were distilled prior to use and were stored over a drying agent.

Statistical analyses. Results were expressed as the sample mean ± the standard error of the mean. The significance of differences in sample means was determined by the t-test and the level of probability (P) at which the null hypothesis be rejected was noted. The reliability of the t-test depends on the standard deviations of the means being similar. The variance ratio test was employed to check the equality of these standard deviations. If, by the variance ratio test, the standard deviations were unacceptably dissimilar, then the result of the t-test was discarded.

RESULTS

Total phosphorus content of whole cells

The phosphorus content of phosphate-limited cells [2.34±0.14 mg (100 mg dry wt)] was only 71% of that of control cells [3.29±0.08; nine determinations].

Effect of phosphate limitation on wall composition

Qualitative analysis. Paper chromatography of hydrolysed wall preparations (2 M-HCl at 105 °C for 3 h in vacuo) revealed the presence of glucose, mannose and glucosamine in hydrolysates of both control and phosphate-limited yeast walls. Treatment of the wall preparations with β-glucanase and α-mannosidase, followed by acid hydrolysis under rather milder conditions, gave N-acetylglucosamine as an additional product. No evidence was obtained for the presence of uronic acids in any of the hydrolysates. Similarly, succinic acid, which is a substituent of the acidic lipomannan of *Micrococcus lysodeikticus* (Owen & Salton, 1975), was not found. However, the spray reagent (Pásková & Munk, 1960) used for the detection of succinic acid did reveal two unidentified, but presumably acidic, components (R_{glucoSe} 0.60 and 0.86; solvent A) which appeared to be present in greater amounts in hydrolysates of walls from phosphate-limited yeast.

Quantitative analysis. The carbohydrate, protein, phosphorus and glucosamine contents of wall preparations are shown in Table 1. Walls from phosphate-limited yeast contained significantly less total carbohydrate (*P* = 0.001) but more protein than control walls. The phosphorus content of phosphate-limited yeast walls was only slightly, but nevertheless significantly (*P* = 0.05), lower, while the glucosamine content was also marginally lower.

To determine the relative amounts of glucan and mannan present, wall suspensions were treated with β-glucanase and α-mannosidase prior to hydrolysis in 1 M-HCl. The enzymic treatment solubilized a considerable proportion of both wall preparations such that the absorbance (A_{560nm}) of the control and phosphate-limited yeast wall suspensions fell by 47.2% and 23.3%, respectively. All of the wall carbohydrate was released during the subsequent acid hydrolysis (Table 2), that from phosphate-limited yeast walls being released more rapidly. The recovery of carbohydrate as glucose plus mannose was between 74% (phosphate-limited) and 81% (control) of the total carbohydrate released from the wall. The mannose contents of the two wall preparations were similar (23 to 24%) but phosphate-limited yeast walls contained much less glucose (28%) than did control walls (45%).

Effect of phosphate limitation on lipid content and composition

Phosphate-limited yeast contained less total lipid [13.30±0.39 mg (100 mg dry wt)] than control cells [14.73±1.03; four determinations]. However, the phospholipid content of phosphate-limited cells [4.79±0.10 mg (100 mg dry wt)]; 12 determinations] was higher than that of control cells [3.90±0.21; three determinations]. A complex series of changes in lipid composition were observed, those in neutral lipids

Cardiolipin and lysophosphatidylcholine were detected in trace amounts only in extracts of control cells.

* Values quoted are means ± the standard error of the mean, with the number of replicate determinations shown in parentheses.

being particularly striking (Table 3). Phosphate-limited cells contained much less sterol ester and triacylglycerol than control cells ($P = 0.001$). The contents of diacylglycerol and free sterol were also lower in the phosphate-limited yeast. Monoacylglycerols were detected only in extracts of control cells. The free fatty acid content of phosphate-limited yeast was 12 to 13 times higher than that of control cells. The difference appeared to be significant ($P = 0.001$) but the validity of the $t$-test was rejected in this instance by the variance ratio test. Phosphate-limited yeast contained more phosphatidylcholine and phosphatidylethanolamine ($P = 0.01$) but less phosphatidylserine ($P = 0.001$) than control cells (Table 4). The phosphatidylinositol and phosphatidic acid contents were similar in both types of cells. Very low concentrations of $N,N$-dimethylphosphatidylethanolamine, lyso phosphatidylcholine and cardiolipin were detected only in extracts of control cells.
DISCUSSION

The most striking change that phosphate limitation of growth induces in the cell-wall composition of many Gram-positive bacteria is the replacement of teichoic acid by phosphorus-free teichuronic acid. However, no such drastic change in cell-wall composition occurs when *S. cerevisiae* is grown under conditions of phosphate limitation. The phosphate content of the wall in *S. cerevisiae* is attributed to the presence of phosphodiester linkages in the outer chains of wall mannan. This phosphomannan component is presumed to be largely responsible for the negative charge or zeta potential of the cell and thus may be considered formally analogous to teichoic acid in bacteria. It would appear that *S. cerevisiae* is unable to incorporate uronic acids into polymers, even under conditions of phosphate limitation. Although uronic acids are known to be constituents of capsular polysaccharides in some yeasts (Phaff, 1971), their presence in cellular components of *S. cerevisiae* has not been reported. Furthermore, attempts to demonstrate the presence of UDPglucose dehydrogenase in phosphate-limited *S. cerevisiae* have been unsuccessful (L. J. Douglas, unpublished observations). Under phosphate limitation, cell-wall phosphate may, however, be partially replaced by an increased proportion of other negatively charged constituents. This conclusion is supported by the work of San Blas & Cunningham (1974) who studied the effect of phosphate deprivation on the composition of mannans produced by *Hansenula holstii*. When this yeast was grown in a complex culture medium from which KH₂PO₄ had been omitted, the wall mannan contained only trace quantities of phosphorus but nevertheless bound in appreciable amounts to a column of DEAE-cellulose. The acidic constituent was not identified.

The major changes in wall composition of phosphate-limited *S. cerevisiae* as compared with control cells were a decreased content of glucan and an increased protein content. Such changes must be examined carefully in the light of the finding by McMurrough & Rose (1967) that the overall wall composition of *S. cerevisiae* is affected by changes in the growth rate. These workers showed that the protein and phosphorus contents of the wall increased as the growth rate was lowered. The total carbohydrate content, on the other hand, was largely unaffected, as were the relative proportions of glucan and mannan. Thus, the observed decrease in carbohydrate content from 83.5% (walls of control cells) to 72% (walls of phosphate-limited cells) can be attributed to a specific effect of phosphate limitation of growth. The increased protein content of walls from phosphate-limited cells, however, may be partially accounted for by the lower growth rate of this culture. Similarly, the relatively high phosphorus content of phosphate-limited yeast walls may reflect a balance between the opposing effects of phosphate limitation, which would tend to decrease the phosphorus content, and a low growth rate, which would tend to increase it.

Hunter & Rose (1972) compared the lipid composition of *S. cerevisiae NCYC 366* grown in a chemostat at rates of 0.25 h⁻¹ and 0.05 h⁻¹. They found that phospholipid synthesis was decreased at the lower growth rate and that this was reflected in lowered levels of phosphatidylethanolamine and, to a much lesser extent, phosphatidylinositol. The phosphatidylserine content was unaffected while the phosphatidylcholine content increased by some 37%. Thus the only change in phospholipid composition of phosphate-limited *S. cerevisiae* which may be attributed to the lower growth rate of this culture is the increased content of phosphatidylcholine. While *S. cerevisiae* may be relatively amenable to changes in phospholipid composition, it would appear to be intolerant of any appreciable diminution in overall phospholipid content. This conclusion is supported by the preliminary report of Johnson *et al.* (1973) which states that only small differences in polar lipid content and composition were detected when *S. cerevisiae NCYC 712* was grown under phosphate limitation. By contrast, when *Pseudomonas diminuta* is subjected to the same growth constraint, the phospholipid content of the organism falls almost to zero (Minnikin *et al.*, 1974).
The most noteworthy change in the lipid composition of phosphate-limited cells was their decreased content of sterol esters and triacylglycerols. Moreover this was unlikely to be a growth-rate effect since Hunter & Rose (1972) demonstrated that lowering the growth rate of *S. cerevisiae* in a chemostat at 30 °C caused an increased synthesis of sterol esters while the triacylglycerol content of the cells was unaffected. Sterol esters and triacylglycerols are two classes of yeast lipid located almost exclusively in intracellular low-density vesicles (Cartledge & Rose, 1973; Clausen et al., 1974). There are two types of vesicle (large and small) present in *S. cerevisiae* (Cartledge et al., 1977). Sentandreu & Northcote (1969) have shown that the large vesicle (or vacuole) undergoes fission during the cell cycle and that the progeny of this fragmentation (small vesicles or sphaerosomes) become concentrated at the neck of the bud, suggesting that they are involved in envelope growth. The decreased content of sterol esters and triacylglycerols in phosphate-limited *S. cerevisiae* implies that there is a diminished population of one or both types of vesicle in these cells. If small vesicles are indeed involved in cell-envelope biogenesis, this could explain the changes in wall composition, notably in glucan content, caused by phosphate limitation of growth. It would be interesting to know whether either type of vesicle contains a relatively high proportion of phosphatidylycerine since the content of this particular phospholipid was substantially decreased in phosphate-limited yeast.

The changes observed in the levels of phosphorus-containing components in walls and lipids of *S. cerevisiae* subjected to phosphate limitation would not appear to account for the appreciable decrease in the total phosphorus content of these cells. It is likely that this can be attributed in part to a decreased synthesis of polyphosphate, a compound known to be accumulated by *S. cerevisiae* (Dawes & Senior, 1973). The exact role of polyphosphate in yeast remains to be established although it is presumed to provide a reserve of phosphorus and/or energy. In the light of the present work it may be of some significance that polyphosphate appears to be located in the large vesicle or vacuole (Urech et al., 1978).

We are greatly indebted to Professor A. H. Rose (University of Bath) for the loan of a chemostat and for his interest in this work. A.M.R. thanks the University of Glasgow for a Faculty of Science Research Studentship.
