On the Serological Specificity of the *Escherichia coli* O8 and O9 Antigens

By Klaus Jann, Barbara Jann, Veronika Winter and Christine Wolf-Ullisch

Max-Planck-Institut für Immunbiologie, Freiburg, West Germany

(Received 27 June 1978)

The O8- and O9-specific lipopolysaccharides of *Escherichia coli* lost their serological activity during liberation of the polysaccharide moieties (α-mannans) by mild acid hydrolysis, as tested by passive haemagglutination and haemagglutination inhibition. The serological activities and specificities were restored by substitution of the polysaccharides with 1 to 2 stearoyl groups per polysaccharide chain. The mannans obtained by biosynthesis *in vitro* were serologically active only when bound to the membrane-associated hydrophobic carrier molecule. Liberation of the polysaccharides from the carrier by treatment with aqueous phenol resulted in loss of the serological activity. The O8- and O9-specific mannans of *E. coli* are thus serologically active when they are part of an amphiphilic molecule and not as free polysaccharides.

**INTRODUCTION**

Among the many O groups of *Escherichia coli* (Ørskov et al., 1967, 1977), groups 8 and 9 have several unique characteristics. Certain types of K antigens – those that are either acidic cell wall lipopolysaccharides or capsular acidic polysaccharides of very high molecular weight – occur only in these O groups, i.e. together with the O8 or O9 antigen (Ørskov et al., 1977). These two O antigens are cell wall lipopolysaccharides. Their O-specific polysaccharide moieties are mannans, bound to core lipid A (Fig. 1). The formulations of their repeating units are (Reske & Jann, 1972; Prehm et al., 1976):

- O8 mannan: $\alpha$-Man$_1$$\alpha$-Man$_2$$\alpha$-Man$_1$$\alpha$
- O9 mannan: $\alpha$-Man$_1$$\alpha$-Man$_2$$\alpha$-Man$_1$$\alpha$-Man$_2$$\alpha$-Man$_1$$\alpha$-Man$_1$$\alpha$

Although the repeating oligosaccharide of the O9 mannan contains that of the O8 mannan, there is no serological relationship (cross-reaction) between the O8 and O9 antigens.

We have found that the serological specificity of both antigens is lost during the liberation of the respective polysaccharides from the lipid A moiety by treatment with mild acid (K. Jann & B. Jann, unpublished data, cited in Ørskov et al., 1977). When studying the membrane-associated biosynthesis of the O9 antigen we found that the product of the *in vitro* synthesis (the O9 mannan), after liberation from the cytoplasmic membrane with aqueous phenol or dilute acid at elevated temperature, did not react with anti-O9 antibody (Kopmann & Jann, 1975).

These findings raised the question of the O8 and O9 specificities. Two alternatives would account for the findings: (i) the specificity is due to a special modifying group, easily split by acid and not added at all in the *in vitro* synthesis; or (ii) the specificity is related to a
special spatial arrangement, maintained only in association with a hydrophobic entity such as lipid A or the carrier molecule of the biosynthesis. The evidence presented in this paper favours the latter interpretation.

METHODS

Bacteria. Escherichia coli r492 (O8:K27::H-) and E. coli r397 (O9:K29::H-) were used for the isolation of the lipopolysaccharides. In vitro syntheses of the O8 and O9 mannans were performed with the phosphomannanesioser-ase-less mutants r860 (from r492; Kopmann & Jann, 1975) and r945 (from r860 by exchange of the rfb gene locus of E. coli O9 for that of E. coli O8 by conjugation with E. coli r549 (O8:K27::H-; Hfr59; Schmidt & Westphal, 1968)].

Media. Strains r492 and r397 were grown on D-1.5 agar (Schlecht & Westphal, 1966) and strains r860 and r945 in A3 medium (Kopmann & Jann, 1975), containing 0.5 % (w/v) glucose.

Chemicals. Stearoyl chloride, dimethylformamide and pyridine were obtained from Roth Co., Karlsruhe, West Germany; GDPmannose from Boehringer; and GDP[^14C]mannose from Amersham-Buchler, Frankfurt, West Germany.

Abbreviations. LPS, Lipopolysaccharide; LPS-alk, alkali-treated lipopolysaccharide; PS-st, stearoylated polysaccharide; O8-TX, O9-TX, products of in vitro O8 or O9 mannans biosynthesis extracted with Triton X-100 in Tris buffer; O8-PW, O9-PW, products of in vitro O8 or O9 mannans biosynthesis extracted with 45 % (w/v) aqueous phenol.

Antisera. Anti-O8-LPS and anti-O9-LPS antisera were obtained by hyperimmunization of rabbits with heat-killed acapsular (K-) E. coli O8:K27::H- and E. coli O9:K29::H- (Mayer & Schmidt, 1973). Antisera against the polysaccharide moieties (mannans bound to core, Fig. 1) were raised by intravenous injection of rabbits with the acid-hydrolysed Salmonella a mutant r595 modified with stearoylated polysaccharides at a polysaccharide/bacteria ratio of 1:10 (w/w), according to Galanos et al. (1971); these antisera are termed anti-PS-st antisera. A goat anti-rabbit globulin antiserum was purchased from the Behringwerke, Marburg, West Germany.

Isolation of lipopolysaccharides and preparation of polysaccharide moieties. Agar-grown bacteria were extracted with 45 % phenol at 65 °C as described by Westphal & Jann (1965). The lipopolysaccharides were obtained from the aqueous phases by repeated centrifugation at 100000 g. The final pellets were taken up in water and freeze-dried. The yields were about 2 % of the bacterial dry weight.

The lipopolysaccharides were degraded in 1 % (v/v) acetic acid at 100 °C for 90 min (Jann et al., 1975; Müller-Seitz et al., 1968; Schmidt et al., 1969) and the flocculent lipid A was then removed by centrifugation in a bench top centrifuge. The polysaccharide which was obtained from the supernatant was purified by chromatography on Sephadex G-50. The material eluted in the void volume was freeze-dried.

Searoylation of polysaccharides. The polysaccharides obtained from the O8- and O9-specific lipopolysaccharides (Fig. 1) were substituted with stearoyl groups as described by Hämmerling & Westphal (1967). In short, 50 mg polysaccharide, dried over P₂O₅ in vacuo at 45 °C, were dissolved in 5 ml anhydrous dimethylformamide; then 0.6 ml anhydrous pyridine and 10 mg distilled stearoyl chloride, dissolved in 0.6 ml dimethylformamide, were added and the mixture was stirred in a sealed ampoule at room temperature for 3 d. The reaction mixture was then diluted with 0.5 ml water and poured into 25 ml ethanol. The precipitate was washed with alcohol, dissolved in 5 ml water containing 1 % (v/v) 1-butanol and purified by chromatography on Sephadex G-50. It was obtained in 90 to 95 % yield. The stearoyl content of the reaction product was determined by gas chromatography of the methyl esters using a Varian Aerograph series 14000 and a Hewlett Packard integrator model 3380; the chromatographic runs were done at 170 °C on EGSSX.

In vitro synthesis of polysaccharides. The incubation mixtures for the in vitro synthesis of the O8 and O9 mannans contained membranes (5 mg protein) obtained from E. coli r860 according to Osborn et al. (1972) or EDTA-bacteria (10⁹ cells) obtained from E. coli r945 according to Robbins et al. (1964) and GDP[^14C]-

substituted the polysaccharides with stearoyl groups according to Hämmerling & Westphal (1967). The purified products contained about 1 to 3 stearoyl groups per polysaccharide chain (Table 1) with a molecular weight of about 10000 to 12000 (Reske, 1970; Reske & Jann, 1972). In contrast to the unsubstituted polysaccharides, the stearoylated polysaccharides gave rise to turbid aqueous solutions. In the analytical ultracentrifuge they sedimented rather quickly with S values ranging between 3 and 10, indicating a micellar state.

Table 2 shows the results of passive haemagglutination tests using the lipopolysaccharides (LPS) and the stearoyl derivatives of the respective polysaccharides (PS-st) in the antisera directed against these antigens (anti-LPS and anti-PS-st). The free polysaccharide moieties of the lipopolysaccharides, i.e. the unsubstituted mannos linked to the core oligosaccharide, were not reactive in any of the antisera. In contrast, the stearoyl derivatives had the same serological activity as the lipopolysaccharides from which the polysaccharide moieties were obtained. They also had the same specificity, with no cross-reaction between the stearoylated polysaccharides obtained from the O8- and O9-specific lipopolysaccharides. The reactivity and specificity of the lipopolysaccharides and those of the stearoyl derivatives from the corresponding polysaccharides were also comparable when tested in the sera obtained with the artificial antigens (anti-PS-st). This was corroborated by gel diffusion in which the homologous lipopolysaccharides and stearoylated polysaccharides showed lines of identity when tested against the anti-polysaccharide antisera obtained with the artificial antigens (data not shown).

In the homologous serological systems, i.e. in the agglutination of erythrocytes coated with the O8 or O9 lipopolysaccharides in anti-O8 or anti-O9 antisera, the unsubstituted and stearoyl-substituted polysaccharides were tested as inhibitors (Table 3). Clearly, the inability of the polysaccharides to inhibit the antigen–antibody reaction was overcome by stearoyl substitution. As with the passive haemagglutination tests, the inhibition studies showed that there was no cross-reaction between the stearoylated polysaccharides.

It is unlikely that the O8 and O9 specificities of the lipopolysaccharides, which are lost during liberation of the polysaccharides from lipid A and restored by stearoylation, are due to some acid-labile determinant present in the lipopolysaccharides and absent in the polysaccharides.

The polysaccharides obtained by in vitro biosynthesis

The products of incubations of EDTA-bacteria or membranes with GDP[14C]mannose were obtained in two ways. (i) Extraction with Triton X-100 in Tris buffer at pH 7·5 and room temperature yielded the mannos bound to the hydrophobic carrier molecule (designated O8-TX and O9-TX). (ii) Extraction with 45% aqueous phenol at 68 °C yielded the free mannos (designated O8-PW and O9-PW). The mobilities of these preparations in sodium dodecyl sulphate-polyacrylamide gel electrophoresis are shown in Fig. 2. O8-TX and O9-TX migrated into the gel, indicating that they were amphiphilic molecules able to interact with sodium dodecyl sulphate. Their electrophoretic mobility corresponded to that of the intermediate of the mannan biosynthesis as described previously (Kopmann & Jann, 1975). O8-PW and O9-PW did not migrate at all.
Table 3. Inhibition of passive haemagglutination by LPS, the polysaccharide moieties (PS) and their stearoyl derivatives (PS-st)

In the haemagglutinating systems, erythrocytes coated with alkali-treated LPS were used in serum diluted one step less than the final dilutions in the passive haemagglutination experiments. Results are expressed as µg inhibitor ml⁻¹ in PBS.

Fig. 2. Sodium dodecyl sulphate–polyacrylamide gel electrophoresis of the radioactive products of in vitro incubations after extraction of the membranes with Triton X-100 (O8-TX, O9-TX; ——) or with 45% aqueous phenol (O8-PW, O9-PW; -----). TD, Tracking dye (pyronin G). The electrophoresis was run on 0.6 x 10 cm gels of 5.8% polyacrylamide in the presence of 1% sodium dodecyl sulphate. The gels were cut into 2 mm slices (fractions) which were hydrolysed in 2 m-HCl and counted as described previously (Kopmann & Jann, 1975).

The purified radioactive products were subjected to the antigen binding test (Rüde et al., 1971). They were first incubated with anti-O8-LPS or anti-O9-LPS antisera or normal serum from rabbits. The antigen–antibody complexes were then precipitated with anti-rabbit Ig antiserum. As shown in Table 4, the free polysaccharides (O8-PW and O9-PW) did not bind anti-O8 or anti-O9 antibodies. However, the polysaccharides bound to the hydrophobic carrier (O8-TX and O9-TX) exhibited distinct and specific binding, although much lower than the theoretical 100% binding. The binding curve obtained with O9-TX is shown in Fig. 3. The results obtained with O8-TX were very similar (data not shown). In both cases about 50% binding of the added radioactive products to specific homologous antibody was observed.

The results of the antigen binding test agree with those from tests of passive haemagglutination and its inhibition. The polysaccharides are serologically active only when they are bound to the carrier and thus are part of an amphiphilic molecule.
Table 4. Antigen binding test of carrier-bound (-TX) and free (-PW) products of the 08 and 09 in vitro synthesis

Antisera were diluted 1:2 and the preparations contained 8000 c.p.m. incorporated from GDP[14C]mannose. Normal rabbit serum was used as a control.

DISCUSSION

The results indicate that the O8 and O9 mannans of Escherichia coli are serologically active only in association with a hydrophobic residue – either lipid A, stearoyl residues or the carrier molecule of the biosynthesis. The role of the hydrophobic part of the molecule may by considered in two ways. It may serve to impose on the polysaccharide a secondary structure which is necessary for the O-antigenic expression, or it may form micelles in which the polysaccharide is presented to the antibody in a closely packed form, thus assuming the O8- or O9-specific state. The latter interpretation seems more likely. Although some acidic polysaccharides with very high molecular weights exhibit regions of helical superstructure (Rees, 1972; Moorhouse et al., 1977; Wolf et al., 1978), such molecular arrangements have not yet been implicated in serological specificity. Also, distinct superstructures are difficult to envisage with neutral polysaccharides having molecular weights of only 10000 to 12000 (Reske, 1970; Reske & Jann, 1972). We demonstrated by analytical ultracentrifugation that the stearoylated O8 and O9 polysaccharides are highly aggregated (3 to 10 S) and the micellar nature of the lipopolysaccharides is well documented (see Jann & Westphal, 1975). Therefore it is much more likely that the serological specificities of the O8 and O9 mannans depend on their micellar presentation. This implies that the primary structure is important (no cross-reaction between both mannans) but not sufficient for the serological expression of the polysaccharides. The results of the antigen binding assay with the biosynthetic products can be discussed in this respect. Only 20 to 50% of the radioactive carrier-bound mannans were precipitated with the homologous antisera. We have recently found (Jann & Kanegasaki, unpublished results) that the sites of biosynthesis of the O9 antigen seem to be located in special areas of the cytoplasmic membrane. Thus the vesicles studied in the
antigen binding assay are likely to be a heterogeneous population with respect to the products of biosynthesis (mannans). Possibly, vesicles with the polysaccharide chains exposed in a dense array did bind the antibodies better than those which contained fewer chains. A similar conclusion was drawn from the interaction of coliphage £8 with its substrate, the O8 antigen of E. coli (Prehm et al., 1976).

The O3 and O5 antigens of Klebsiella are lipopolysaccharides with α-mannans which are structurally (Curvall et al., 1973; Lindberg et al., 1972) and serologically closely related to the O8 and O9 antigens of E. coli. We have found that these Klebsiella O antigens also lose their O specificity when the polysaccharides are detached from lipid A by mild acid hydrolysis. Thus it is interesting to note that all the bacterial O antigens in which we assume a close apposition of polysaccharide chains to be essential for their immunological expression have α-mannans as their O-specific polysaccharides.
