Characterization and Persistence of Actinophage RP2
Isolated from Streptomyces rimosus ATCC 10970

(Received 26 September 1978; revised 30 January 1979)

While searching for true lysogens among oxytetracycline-producing Streptomyces rimosus strains, free phage particles were detected and isolated from a liquid culture of S. rimosus ATCC 10970 (R7). The actinophage, designated RP2, appears to be a typical temperate DNA phage producing turbid plaques on the sensitive strain S. rimosus R6. Electron microscopic examination of RP2 lysates showed that it belongs to group B of Bradley's morphological classification. The rate of RP2 adsorption at 28 °C appeared to be low. The length of the latent period was about 6 h and the average burst size about 120 phage particles.

The lysogenic nature of the host–virus system described was established on the basis of the following characteristics: spontaneous lysis frequency of $2 \times 10^{-6}$ per cell, resistance to curing with phage-specific antiserum, spontaneous curing frequency of less than 0.05% and immunity to superinfection with the homologous phage. Clear-plaque mutants of RP2, which failed to lysogenize sensitive cultures, arose at a frequency of $10^{-5}$.

INTRODUCTION

The first reports of the occurrence of true lysogeny in actinomycetes appeared simultaneously from three independent laboratories in 1956. It was soon established that most industrial cultures of antibiotic-producing streptomycetes were lysogenic or pseudo-lysogenic. The distribution of lysogenic Streptomyces species in culture collections has since been extensively studied especially in relation to antibiotic production (Welsch, 1969). However, the genetically well-characterized strain Streptomyces coelicolor A3(2) (Sermonti, 1969; Hopwood et al., 1973) appears to be the only actinomycete in which the genetic control of lysogeny has been investigated. Lomovskaya et al. (1970) were the first to describe a temperate phage isolated from S. coelicolor A3(2), while Dowding & Hopwood (1973) reported the isolation of the free virion VP5, capable of lysogenizing the same strain.

While searching for true lysogens among the oxytetracycline-producing S. rimosus strains, we detected free phage particles in the liquid culture of S. rimosus ATCC 10970 (R7). In an attempt to establish this strain and its phage as a host–virus model system for investigating the impact of lysogeny on the industrial production of antibiotics, it has been necessary to grow and characterize the newly detected phage. In this report we describe the conditions necessary for its assay, propagation and preservation, as well as some of the phage characteristics, and show that S. rimosus, which, after S. coelicolor, is genetically the best known Streptomyces species (Alačević, 1969; Friend & Hopwood, 1971; Alačević et al., 1973) harbours a prophage (designated RP2) in a truly lysogenic state.
METHODS

Bacterial strains. Two independent wild-type isolates of Streptomyces rimosus were used: the lysogenic strain ATCC 10970 (R7), and the non-lysogenic strain R6 obtained from the Culture Collection of the Faculty of Technology, Zagreb. Both were maintained on agar plates for 10 d at 28 °C, and well-separated colonies were used for liquid culture propagation. Mycelium was incubated with shaking in experiments to determine growth curves.

Media. Complete medium (CM) contained (g l⁻¹ in distilled water): malt extract (Difco), 10; yeast extract (Difco), 4; glucose, 4. Complete agar (CA) was complete medium solidified by the addition of 2 % (w/v) agar (Difco); soft agar contained only 0-7 % agar. Liquid medium (LM) contained (g l⁻¹ in distilled water): corn steep liquor (approx. 50 % solid), 16; dextrin, 40; CaCO₃, 7; (NH₄)₂SO₄, 2. Phage lysates were prepared and diluted in nutrient broth (Difco). All media and diluents were adjusted to pH 7.2 after sterilization.

Phage assay. In the soft agar overlay technique (Adams, 1959), sensitive cells (0.5 ml) from the early-stationary phase [approx. 2 × 10⁷ colony-forming units (c.f.u.) ml⁻¹] were mixed in soft agar with 0-1 ml samples of diluted phage lysates, poured on the agar base layer and incubated at 28 °C for 2 to 3 d.

Lysate preparation. Lysates prepared by the confluent plate method (Eisenstark, 1967) contained about 10⁸ to 10⁹ plaque-forming units (p.f.u.) ml⁻¹ and were sterilized by filtering through 25 mm Millipore filters (pore size 0.45 μm) or through Erekfeld filters.

When necessary, lysates were concentrated and partially purified as follows. After centrifuging for 70 min in a WKF G420 Winkel Rotor (6 × 100 ml) at 17000 rev. min⁻¹ (rₑₛ, 64200 g), pellets were resuspended in 5 mm-Tris/HCl buffer, pH 7.4, containing 1 mm-MgSO₄ and 10 mm-NaCl, treated with pancreatic ribonuclease and deoxyribonuclease I (Boehringer) and then recentrifuged twice more. Concentrated phages were purified by 'rate zonal' centrifugation through a discontinuous gradient of sucrose by banding the phage at 17500 rev. min⁻¹ (rₑₛ, 31157 g) for 1-5 h in the Swingout-Rotor (3 × 34 ml) of WKF G420 centrifuge. The phage band was diluted 10-fold with Tris/HCl buffer and recentrifuged. Ultraviolet absorption spectra of purified preparations were determined using a Pye Unicam SP8-100 ultraviolet spectrophotometer.

Electron microscopy. Droplets of purified phage suspension were negatively stained with neutral 2 % (w/v) potassium phosphotungstate solution on carbon-coated copper grids. Excess suspending fluid was removed with a piece of filter paper, and the preparation was air-dried. Grids were examined in a Siemens Elmiskop I electron microscope.

Adsorption. Adsorption rates were established by measuring the phage particles from the supernatant fraction of adsorption mixtures according to Adams (1959). Sensitive cells from the exponential phase of growth (approx. 2 × 10⁶ c.f.u. ml⁻¹) were infected with phage at a low multiplicity (< 0.1) and incubated at 28 °C with shaking. Samples were withdrawn after 7.5, 15, 30, 45 and 60 min, centrifuged and tested.

One-step growth experiment (Adams, 1959). Phage was added to exponentially growing sensitive cultures to give a low multiplicity of infection (about 0-1). After 60 min adsorption in a mixture with KCN (final concentration 0-1 mm), free phage particles were eliminated by adding antiserum (1:50). After 15 min, the infected cells were diluted 10⁻³ (first growing flask) or 10⁻⁴ (second growing flask) and incubated at 28 °C with shaking. Samples were assayed at 30 min intervals for plaque forming ability.

Nucleic acid determination. To determine the type and configuration of nucleic acid in a phage particle, we used the method of Bradley (1966) with the double-stranded DNA coliphage λ and the single-stranded RNA coliphage φ₆ (kindly supplied by Dr E. Salaj-Smig) as controls.

Deoxyribose was measured using the diphenylamine reaction (Burton, 1956), and ribose by the orcinol reaction (Dische, 1953).

Ultraviolet-irradiation. A suitably diluted cell suspension of S. rimosus R7 was plated on CA and irradiated with a Philips TUV15 germicidal lamp. The dose rate, measured by a dosimeter with a Latarjet No. 11 photovoltaic cell, was 4.1 J m⁻² s⁻¹. All operations were carried out under yellow light from a G.E. ‘Gold’ fluorescent lamp. Irradiated cells were incubated in the dark at 28 °C for 48 h.

Preparation of RP2 antiserum. This was done essentially as described by Adams (1959), except that Freund’s incomplete adjuvant was used.

RESULTS

Isolation and morphology of RP2. An actinophage, which we designated RP2, was isolated from a liquid culture of Streptomyces rimosus R7 plated on a lawn of S. rimosus R6; its plaques on R6 had a turbid centre surrounded by a clear halo, and an average diameter, when well-developed, of between 3 and 5 mm (Fig. 1).
Electron microscopic examination of RP2 lysates showed particles with a hexagonal head and a long, flexible, non-contractile tail (Fig. 2). Measurements of 50 particles indicated an average head diameter of $71.5 \pm 1.5$ nm, a tail length of $250 \pm 4.0$ nm and a tail width of $16 \pm 2.0$ nm. There appeared to be a special fixation structure in the distal extremity of tails, but this was not clearly distinguishable on complete particles.

Influence of environmental factors on RP2 stability and efficiency of plating. To determine the stability of RP2 in liquid, 0.1 ml samples of RP2 lysate were added to 10 ml of various salt solutions and buffers, and after 24 h incubation the resulting mixtures were assayed for viable phage (Table 1). Actinophage RP2 was stable in most of the salt solutions tested, but irreversible inactivation occurred in 100 mM-NaCl and in 5 mM phosphate and citrate/phosphate buffers.

RP2 was stable in 5 mM-Tris/HCl buffer over the pH range 7 to 9. Tris/HCl buffer, pH 7.4, supplemented with 1 mM-MgSO$_4$, 10 mM-NaCl and 10 μg gelatine ml$^{-1}$ was found to be satisfactory for storage of the phage for at least 2 years.

The effect of Na$^+$, Mg$^{2+}$ and Ca$^{2+}$ on the efficiency of plating (e.o.p.) of RP2 was determined on CA and CA containing 5 mM NaCl, MgSO$_4$ or Ca(NO$_3$)$_2$. The relative e.o.p.
Table 1. Stability of actinophage RP2 in various diluents
Phage lysate (0.1 ml) was added to 10 ml diluent and the mixture was assayed for viable phage after 24 h.

values obtained with Na⁺, Mg²⁺ and Ca²⁺ were 0.9, 1.2 and 1.1, respectively, indicating that the e.o.p. was not affected by these cations.

Effect of the age of the host culture on the plating efficiency of RP2. Streptomyces rimosus R6 was grown in LM and suspensions corresponding to the early-exponential, exponential, late-exponential and stationary phases of growth were tested. The number of R6 c.f.u. ml⁻¹ increased from about 10⁷ to 10⁹ during this time. The effect of the density of R6 in the soft agar on RP2 e.o.p. was therefore investigated. Results showed that the phage e.o.p. was independent of the number of R6 c.f.u. as long as a lawn of the indicator strain was formed. However, RP2 plaque morphology was affected. Typical, fully developed plaques were formed only when soft agar was inoculated with more than 10⁸ c.f.u. ml⁻¹. RP2 e.o.p. was not markedly influenced by the host culture age. Therefore, S. rimosus R6 mycelium from the stationary phase of growth was used routinely, giving a smooth uniform lawn and typical plaque morphology.

Adsorption. Adsorption rate constants were determined for S. rimosus strains R6 and R7 (Fig. 3). In the absence of a host, there was no loss of viable phage during 60 min incubation. When logarithms of the percentage of unadsorbed phage were plotted against time, the curves were linear between 0 and 30 min for both strains, after which the adsorption rates appeared to fall. Adsorption rate constants were 8.8 x 10⁻¹¹ and 1.1 x 10⁻¹⁰ ml min⁻¹ for R6 and R7, respectively, showing a relatively low rate of attachment under these conditions.

Attempts were made to desorb any reversibly adsorbed particles. However, less than 0.1% of reversibly adsorbed particles were observed, either on diluting the adsorption mixture 100-fold in plain broth before separation of free phages, or by looking for eluted particles after resuspending the sediment of an adsorption mixture in nutrient broth.

One-step growth experiment. The one-step growth curve of RP2 at 28 °C gives a value of 6 h for the minimum latent period, followed by a 4 h period of increase (Fig. 4). The average burst size was 100 to 120 phage particles.

Since the recovery of infective centres at a multiplicity of infection of 0.1 was very low under the conditions used, it seemed likely that filaments of various lengths adsorbed and inactivated from one to several phage particles; the resulting complex would be identifiable as only one infective centre. However, the occurrence of abortive infections has not been ruled out.

Determination of RP2 nucleic acid type. A concentrated and purified RP2 preparation exhibited a high degree of homogeneity. Its ultraviolet absorption spectrum showed a minimum at 241 nm and a maximum at 261 nm. The ratio of absorbance of 260/280 nm was 1.24.

The type and configuration of RP2 nucleic acid was determined by fluorescent staining with acridine orange (Bradley, 1966). Comparison with the double-stranded DNA col-
phage λ and the single-stranded RNA coliphage f2 indicated that the actinophage RP2 nucleic acid was double-helical DNA. The results were confirmed by estimations of deoxyribose and ribose in the preparation, which corresponded to 62 μg DNA ml⁻¹ and 2 μg RNA ml⁻¹.

**Host-range.** The ability of RP2 to form plaques on 23 *Streptomyces* species was determined. The e.o.p. of RP2 was < 10⁻⁹ for each host except *S. rimosus* R6. Its host-range therefore appears to be quite narrow.

**Spontaneous phage release.** A suspension of *S. rimosus* R7 from a liquid culture was centrifuged at low speed and then the supernatant was membrane-filtered and assayed on strain R6 for free phage. Suitable dilutions of the washed suspension (approx. 1 × 10⁹ c.f.u. ml⁻¹) were plated and immediately overlaid with R6 to test for spontaneous phage release. The plaque counts from three independent experiments demonstrated that supernatants of strain R7 always contained about 3 × 10⁸ free phage particles ml⁻¹. However, 30 to 40% of colonies derived from the plated cells released phage spontaneously in less than 3 d. When further platings of R7 cells were overlaid with the sensitive strain R6 after 5 to 6 d growth and incubated for a further 2 to 3 d, every colony was surrounded by a zone of phage lysis.

The kinetics of spontaneous production of RP2 in a liquid culture of *S. rimosus* R7 is shown in Fig. 5. The maximum number of spontaneously produced phage was 4·8 × 10⁹ p.f.u. ml⁻¹ seen after 48 h incubation. At that time, cells were in the stationary phase of growth and the viable cell count was about 2 × 10⁹ to 3 × 10⁹ c.f.u. ml⁻¹. After prolonged incubation the phage titre continuously decreased. Since the burst size of RP2 was about 100 particles (c.f.u.)⁻¹, the spontaneous lysis frequency of R7 was of the order of 10⁻⁶ (c.f.u.)⁻¹ at 48 h.

When spontaneous phage release was tested in the presence of phage-specific antiserum, no free phage was detected. After removal of antiserum, phage were produced at the usual rate. Moreover, colonies obtained by streaking out from liquid cultures containing antiserum retained the ability to produce phage, providing further evidence of true lysogeny of *S. rimosus* R7.
Fig. 5. Kinetics of spontaneous RP2 production by *Streptomyces rimosus* R7. The strain was grown in liquid medium (1% inoculum) with shaking at 28 °C. Numbers of c.f.u. (○) and of free phage particles (●) were estimated at 6 h intervals.

Fig. 6. Single colony isolates from *Streptomyces rimosus* R7 were inoculated on a ‘master-plate’ and overlaid with the phage-sensitive strain *S. rimosus* R6. The three colonies showing no sign of lysis were R6 isolates included as controls.

**Clear-plaque mutants.** These arose spontaneously on plates seeded with a large number of RP2 particles (Fig. 1) at an average frequency, tested by plating 10 wild-type plaques, of approx. $2 \times 10^{-5}$.

**Sensitivity to homologous phage.** *Streptomyces rimosus* R7 appeared to be immune to superinfection with RP2 and its clear-plaque mutants. Immunity to superinfection was also confirmed in all auxotrophic mutants of the strain R7 so far tested, although adsorption was normal.

**Phage curing.** The frequency of spontaneous curing of *S. rimosus* R7 cells from RP2 was tested by making serial single colony isolations. None of 2708 colonies overlaid with
Actinophage of *Streptomyces rimosus*

an indicator top layer after 3 d failed to produce phage (Fig. 6). Spontaneous curing was therefore \(< 0.05\%\).

After ultraviolet treatment of mycelial fragments to \(10^{-6}\) to \(10^{-5}\) survival, about 0.1 \% (3/2919) of colonies failed to produce phage. These were all immune to superinfection by RP2 although they could still adsorb it; presumably they carried a defective RP2 prophage.

DISCUSSION

Actinophage RP2 isolated from a liquid culture of *Streptomyces rimosus* R7 has been grown and partially characterized. Its morphology and double-stranded DNA content place it in group B of Bradley's morphological classification (Bradley, 1967). It is a tadpole-shaped particle, like most other actinophages (Welsch, 1969; Hopwood et al., 1973; Korn et al., 1978), apart from the tail-less actinophage \(\phi 17\) (Bacq & Horne, 1963) and rod-like nocardiphage described by Azarowitz et al. (1954).

General properties of the RP2 life-cycle were determined in one-step growth experiments. From the adsorption rate constants it was apparent that RP2 attachment was slow. This appears to be typical of all actinophages (Welsch, 1969), and different from other phage-bacteria systems (Dowding, 1973). Although the latent period of actinophage-actinomycete systems is usually long (Welsch, 1969), RP2, with its 6 h latent period, is the slowest multiplying actinophage so far described.

Spontaneous release of RP2 particles from *S. rimosus* R7 occurred only in part of the population as shown by plating with the sensitive strain. Lomovska? et al. (1972) and Dowding & Hopwood (1973) observed that only a few per cent of *S. coelicolor* A3(2) spores plated gave rise to colonies releasing phage. The fact that about 30 to 40\% of the R7 cells plated produced colonies releasing phage may be explained in terms of the faster growth of the lysogenic strain than the sensitive strain. In these experiments mycelial fragments were used instead of spores, which increased the growth rate of the lysogenic strain considerably.

In various lysogenic systems \(10^{-5}\) to \(10^{-2}\) cells per generation undergo spontaneous lysis (Adams, 1959). Since streptomycetes are growing in a complex mycelial form and thus do not have a defined generation time, spontaneous induction was calculated as the frequency of lysis among viable c.f.u. during the period of increase in phage production. The highest titre of RP2 free phage particles (4.8 \(\times 10^6\) p.f.u. ml\(^{-1}\)) is considerably lower than titres of free phages (up to \(10^{10}\) p.f.u. ml\(^{-1}\)) obtained in pseudolysogenic conditions (Bott & Strauss, 1965). The value for spontaneous lysis frequency of about \(10^{-6}\) (c.f.u\(^{-1}\)) calculated from these figures is probably a gross underestimate, but nevertheless is very low compared with values obtained in pseudolysogenic or carrier state systems (Bott & Strauss, 1965).

Although liquid cultures of R7 always contained free phage, detectable lysis was not observed. *Streptomyces rimosus* R7 is thus immune to infection with the homologous phage RP2. This immunity was also shown by the inability of RP2 to form plaques when plated on the R7 strain.

The lack of spontaneous curing of R7 cells provides further evidence of the truly lysogenic nature of the host-virus system studied. The curing rate (\(< 0.05\%\)) was very low in comparison with spontaneous curing frequencies of 30 to 90\% among non-lysogenic phage-carrying strains (Bott & Strauss, 1965; Baess, 1971).

It was impossible to cure the cells even after exposure to high doses of ultraviolet light. Although this procedure has proved successful in some cases (Zinder, 1958; Lomovskaya et al., 1971), we were unable to isolate a single cured variant out of 2919 colonies tested.

Final evidence of the true lysogeny of *S. rimosus* R7 comes from experiments using RP2-specific antiserum. The RP2 titre in successive liquid cultures remains remarkably constant if one takes into account the mycelial nature of actinomycetes. However, free
phage readily disappears from cultures containing antiserum, while the transfer from antiserum-containing culture to plain broth immediately results in the production of RP2 particles. Moreover, R7 cells isolated from the antiserum-containing culture give rise to colonies spontaneously liberating phage.

Clear-plaque mutants arise spontaneously from RP2 wild-type stocks. The fact that these lose their ability to lysogenize sensitive cells but are still unable to lyse strains carrying the wild-type prophage suggests, by analogy with phage λ (Hershey, 1971), that these mutations affect some steps of the lysogenization process. Similar mutants have been isolated from the S. coelicolor A3(2) temperate phages φC31 and VP5 (Lomovskaya et al., 1970; Dowding & Hopwood, 1973). However, clear-plaque mutants of Bacillus subtilis phage SP10, which does not establish a stable relationship with the host, were reported (Kawakami & Landman, 1968). Consequently, their appearance cannot be taken as proof of a truly lysogenic condition.

All RP2 characteristics reported here indicate that it is a typical temperate actinophage comparable to those already described. The knowledge of its properties as well as conditions necessary for its routine propagation and assay will facilitate further studies. The results proving true lysogeny in the RP2–S. rimosus R7 host–virus system will enable the study of prophage behaviour during the production of antibiotic in relation to inducibility, appearance of virulent mutants or other lytic factors.

The skilled technical assistance of M. Debelli, V. Horvat and M. Smolčić is gratefully acknowledged. We would like to thank Dr N. Ljubešić for electron micrograph preparation, Dr S. Petričević for antiserum preparation and Professors M. Alaević and G. Sermonti for critically reading the manuscript.
