(Received 6 March 1980)

*Chromobacterium iodinum* (Davis) differs to such an extent from the type species of *Chromobacterium*, *Chr. violaceum* (Bergonzini), that it cannot be retained in this genus. Chemical, morphological and numerical phenetic data indicate a close relationship between *Chr. iodinum* and the species *Brevibacterium linens* (Wolff, Breed). It is suggested that *Chr. iodinum* be reclassified in a redefined genus *Brevibacterium* as *B. iodinum* (Davis) nom.rev.; comb.nov.

**INTRODUCTION**

The generic assignment of the bacteria named *Chromobacterium iodinum* (Davis, 1939) has always been controversial (Tobie, 1945; Gilman, 1953; Sneath, 1956, 1960; Steele, 1961; Gerber & Lechevalier, 1964; Colwell *et al.*, 1969). In the 8th edition of *Bergey's Manual of Determinative Bacteriology* the species is listed as *incertae sedis* (Sneath, 1974) and it does not appear in the Approved List of Bacterial Names (Skerman *et al.*, 1980).

*Chromobacterium iodinum* was isolated from milk during a routine bacteriological examination (Davis, 1939), but the original source could have been water, soil, human or animal. Davis (1939) described the organisms as Gram-negative, non-sporing, non-motile rods and stated that the most distinctive feature was the production of dark purple crystals on the surface of colonies and in the adjacent medium. He also noted the similarity between the pigment and crystals of 'ordinary iodine'. Chemical investigations (Clemo & McIlwain, 1938; Tobie, 1945; Clemo & Daglish, 1950) showed that the pigment, named iodinin, was a phenazine derivative quite unrelated to violacein, the pigment component of *Chromobacterium violaceum* (Tobie, 1938, 1939). Phenazines and their derivatives were thought to be fairly uncommon and for this reason Tobie (1945) suggested that all bacteria producing these compounds should be included in the genus *Pseudomonas*. He therefore proposed the reclassification of *Chr. iodinum* as *Pseudomonas iodina* and later *Pseudomonas iodinum* (Tobie, 1939, 1945). However, phenazines and their derivatives have subsequently been shown to be present in a variety of Gram-negative and Gram-positive bacteria (Gerber & Lechevalier, 1964; Lechevalier *et al.*, 1971).

Later studies of *Chr. iodinum* (*P. iodinum*), notably those of Gilman (1953), Steele (1961) and Sneath (1956, 1960), indicated that the organism was a Gram-positive rod with a coryneform morphology. Gilman (1953), however, thought the species should be retained in the genus *Pseudomonas*, despite its Gram-positive staining reactions. Sneath (1960)
suggested that it might well be classified in the genus *Corynebacterium* or in the genus *Brevibacterium* but did not pursue the matter further.

Colwell et al. (1969), as a result of a comprehensive study of three cultures named *Pseudomonas iodinum*, proposed that the bacteria be reclassified in the genus *Arthrobacter*, as *Arthrobacter iodinum*. However, in the numerical taxonomic study of Jones (1975), one strain of *Chr. iodinum* (labelled ‘coryneform species’ NCIB 8179) was recovered in the same cluster as strains of *Brevibacterium linens* and showed no close relationship to any of the other coryneform taxa investigated, including *A. globiformis* and several other strains of the genus *Arthrobacter*. Nevertheless, Jones (1975) stated that the recovery of *P. iodinum* in the same cluster as *B. linens* ‘is not easily explained’ because ‘... All attempts to demonstrate the presence of the *B. linens* carotenoid-like material failed. It is possible that it is a carotenoid-less mutant but it would additionally have had to develop the purple crystals of iodinin.’ Further support for a relationship between the two species comes from the report that *Chr. iodinum*, like *B. linens*, has a directly cross-linked meso-diaminopimelic acid-containing peptidoglycan (Fiedler et al., 1970; Schleifer & Kandler, 1972), and that the guanine plus cytosine (G+C) content of the DNA is 63 mol % (Colwell et al., 1969), similar to that of *B. linens* (Crombach, 1972; Yamada & Komagata, 1970, 1972).

It is now recognized that the results of lipid analyses are of value in the taxonomy of the coryneform bacteria (Collins et al., 1977, 1979a, b, 1980a; Minnikin et al., 1978, 1979). The cellular morphology and lipid composition of *Chr. iodinum* were therefore investigated in an attempt to clarify its taxonomic position especially with regard to its apparent taxonomic relationship with *B. linens*.

**METHODS**

*Strains.* *Brevibacterium linens* strains ATCC 9172, ATCC 9174 and NCIB 8546 and *Chromobacterium iodinum* strain NCDO 613 and NCIB 8179 were obtained from the relevant culture collections.

*Morphological examination.* Colonial and cellular morphology were examined and Gram-stains were done as described by Cure & Keddie (1973) and Jones (1975).

*Cultivation.* Cultures for lipid analyses were grown in shake flasks in nutrient broth no. 2 (Oxoid) supplemented with glucose (2 mg ml⁻¹) for 2 to 3 d at 30 °C. Cultures were checked for purity at maximum growth, collected by centrifugation (6000 g for 10 min), washed with distilled water and freeze-dried.

*Analysis of fatty acid methyl esters.* Dry organisms (50 mg) were examined using the acid methanolyis and thin-layer chromatography (t.l.c.) procedure described by Minnikin et al. (1975). Fatty acid methyl esters were purified and examined by gas–liquid chromatography as previously described (Collins et al., 1980b).

*Analysis of polar lipids.* Free lipids were extracted from dry organisms (50 mg) using a modification (Kates, 1972; Card, 1973; Minnikin et al., 1979) of the procedure of Bligh & Dyer (1959). Polar lipid patterns were obtained by two-dimensional t.l.c. of lipid extracts using HPTLC Kieselgel 60 F₃₄₅ (Merck Art. 5628) plates (10×10 cm). Chromatograms were developed in the first dimension with chloroform/methanol/water (65:25:4, by vol.), and in the second with chloroform/acetic acid/methanol/water (80:15:12:4, by vol.) Spraying with 10% molybdophosphoric acid in ethanol followed by heating at 125 °C for 15 min revealed the presence of all lipids. Specific spray reagents for lipid phosphate (Dittmer & Lester, 1964), α-glycols (periodate–Schiff) (Shaw, 1968), sugars (α-naphthol and anisaldehyde/H₂SO₄) (Jacin & Mishkin, 1965; Stahl & Kaltenbach, 1961) and free amino groups (ninhydrin in water-saturated butanol) were also used.

*Analysis of isoprenoid quinones.* Isoprenoid quinones were extracted and purified as described by Collins et al. (1977) and were further examined by reverse phase partition chromatography using Merck RP-18F₃₄₅ reverse phase thin-layer plates (10×10 cm) and a polar developing mixture of acetone/water (99:1, v/v) (Collins et al., 1980a). Mass spectra of the isoprenoid quinones were recorded on an AEI MS9 instrument using a direct insertion probe, an ionizing voltage of 70 eV and a temperature range of 200 to 220 °C.

**RESULTS**

Phase contrast micrographs indicated that *Chromobacterium iodinum* exhibited a coryneform morphology and a rod/coccus cycle (see Fig. 3), similar to that described for *Brevibacterium linens* (see Cure & Keddie, 1973).
**Brevibacterium iodinum** nom.rev.; comb.nov.

Fig. 1. Gas-liquid chromatographic analysis of representative fatty acid methyl esters of *Chromobacterium iodinum* (a) and *Brevibacterium linens* (b). The column (6.5 m) containing 7% ethylene-glycol adipate on 80 to 100 mesh Chromosorb G AW-DMCS was operated isothermally at 200 °C. Abbreviations: *i*, iso acid; *ai*, anteiso acid; *s*, straight-chain acid.

Whole-organism methanolyisates of the test strains showed the presence on thin-layer chromatographs of single spots corresponding to non-hydroxylated fatty acid methyl esters (Goodfellow et al., 1976; Minnikin et al., 1978). All strains produced closely related fatty acid profiles; representative profiles are illustrated in Fig. 1 and quantitative data are shown in Table 1. The fatty acids were composed primarily of anteiso- and iso-methyl-branched acids (98.4 to 98.8%) although straight-chain acids were also present in small amounts (1.2 to 1.6%). The major fatty acids in all strains were 14-methylhexadecic (anteiso C_{14}) and 12-methyltetradecanoic (anteiso C_{12}) acids (Table 1).

Strains possessed remarkably similar, characteristic polar lipid patterns, representatives of which are shown in Fig. 2. Diphosphatidylglycerol (DPG) and phosphatidylglycerol (PG) were readily identified in all the extracts by their chromatographic behaviour and staining properties. In addition, all strains produced a characteristic lipid which gave negative reactions to the lipid phosphorus and ninhydrin sprays but positive reactions to the periodate–Schiff and α-naphthol reagents. These glycolipids (G) gave a green coloration with the anisaldehyde/H₂SO₄ reagent indicating that they may contain mannose residues. This possibility was supported by co-chromatography of the unidentified glycolipid with dimannosyl diacylglycerol from *Corynebacterium aquaticum* (Khuller & Brennan, 1972; Minnikin et al., 1978).

No evidence was found for the presence of ubiquinones (coenzyme Q) in the extracts of any strains; components that co-chromatographed with vitamin K were the only isoprenoid quinones detected. Ultraviolet absorption spectra of the purified quinones showed absorption maxima at 242, 248, 260, 270 and 326 nm, in accord with published data for menaquinones (Dunphy & Brodie, 1971). The mass spectra of the menaquinone samples

tr, Trace amount.
* According to Miwa et al. (1960); EGA refers to ethyleneglycol adipate column.
† Abbreviations for fatty acids are explained by the following examples: 15:0 for the straight-chain pentadecanoic acid; i-15 for the iso acid 13-methyltetradecanoic acid; ai-15 for the anteiso acid 12-methyltetradecanoic acid.

Fig. 2. Two-dimensional thin-layer chromatograms of polar lipids from Chromobacterium iodium (a) and Brevibacterium linens (b). Chloroform/methanol/water (65:24:4, by vol.) was used in the first dimension, and chloroform/acetic acid/methanol/water (80:15:12:4, by vol.) was used in the second dimension. Abbreviations: DPG, diphosphatidylglycerol; PG, phosphatidylglycerol; G, glycolipid.

showed intense peaks at m/e 187 and 225 derived from the naphthoquinone nucleus, as expected from published data (Azerad & Cyrot-Pelletier, 1973). Strong peaks corresponding to molecular ions (M⁺) were also observed. Details of the mass spectral analyses are shown in Table 2. Strains contained major amounts of dihydrogenated menaquinones with eight isoprene units [abbreviated as MK-8(H₂)], although small amounts of MK-8 and MK-7(H₂) were also detected in the mass spectra and on reverse phase partition chromatography.
DISCUSSION

The recovery of menaquinones as the sole isoprenoid quinones from the *Chr. iodinum* strains confirms the views of several workers that this organism is Gram-positive (Gilman, 1953; Sneath, 1956, 1960; Jones, 1975; Weitzman & Jones, 1975). The Gram-negative genera *Chromobacterium* and *Pseudomonas* contain ubiquinones (coenzyme Q) as their sole isoprenoid quinones (Bishop et al., 1962; Lester & Crane, 1959; Page et al., 1960; Whistance et al., 1969).

The presence of MK-8(H₂) as the major menaquinone isoprenologue in strains of *Chr. iodinum* (Table 2) together with their coryneform morphology, fatty acid (Table 1) and polar lipid profiles (Fig. 2) support the results of numerical taxonomic (Jones, 1975), peptidoglycan (Fielder et al., 1970) and DNA base composition (Colwell et al., 1969; Yamada & Komagata, 1970) studies, in indicating a taxonomic relationship between *Chr. iodinum* (Davis) and *B. linens* (Wolff) Breed. However, our results and those of Fielder et al. (1970) and Jones (1975) do not support the suggestion of Colwell et al. (1969) that *Chr. iodinum* should be reclassified in the genus *Arthrobacter*. *Arthrobacter globiformis* (the type species of the genus) and related species contain MK-9(H₂) as their major menaquinone isoprenologue (Yamada et al., 1976; Collins et al., 1979a) and diphosphatidylglycerol, phosphatidylglycerol and phosphatidylinositol as their major phospholipids, together with a complex mixture of glycolipids consisting of mono- and digalactosyl diacylglycerols and dimannosyl diacylglycerol (Kostiw et al., 1972; Minnikin et al., 1978). In addition, the peptidoglycan of *A. globiformis* and related species contains L-lysine (Fiedler et al., 1970; Schleifer & Kandler, 1972).

On the basis of the results presented here and the results of the earlier numerical taxonomic (Jones, 1975), cell wall (Fiedler et al., 1970; Schleifer & Kandler, 1972) and DNA base composition (Colwell et al., 1969; Yamada & Komagata, 1970) studies, we consider that the bacteria now designated *Chr. iodinum* should be reclassified in the same genus as *B. linens*.

*Brevibacterium linens* is the type species of the genus *Brevibacterium* Breed 1953. This genus is presently considered to be incertae sedis, and therefore *B. linens*, the type species, is also so designated (Rogosa & Keddie, 1974). However, there is much evidence that *B. linens* strains form a distinct group which could form the nucleus of a redefined genus *Brevibacterium*, as first suggested by Yamada & Komagata (1972) and later by Jones (1975), Keddie & Cure (1977) and Sharpe et al. (1978). We therefore consider that the bacteria now referred to as *B. linens* (Wolff) Breed and *Chr. iodinum* (Davis) should be classified as two separate species in a redefined genus *Brevibacterium*.

*Chromobacterium iodinum* differs from *B. linens* in the production of a characteristic phenazine derivative (iodinin) and also lacks the carotenoid characteristic of *B. linens*.

(Jones, 1975). In addition, they can be differentiated on the basis of certain physiological tests (see species description). A problem arises because the name Chromobacterium iodinum (Davis) is not included in the Approved List of Bacterial Names (Skerman et al., 1980). Therefore we propose the revival of the species epithet ‘iodinum’ and at the same time the transfer of bacteria so designated to the genus Brevibacterium as Brevibacterium iodinum nom.rev.; comb.nov. (see Rules 28a and 41b; Lapage et al., 1975).

**Emended description of the genus Brevibacterium** (Breed, 1953; Skerman et al., 1980) – Brevibacterium emend.

The following description is based on the literature descriptions of Brevibacterium linens (Wolff) Breed and Chromobacterium iodinum (Davis) (Davis, 1939; Gilman, 1953; Sneath, 1956, 1960, 1974; Steele, 1961; Mulder et al., 1966; Colwell et al., 1969; Yamada & Komagata, 1970; Fiedler et al., 1970; Crombach, 1972; Jones, 1975; Collins et al., 1977, 1979 a; Keddie & Jones, 1980; the present work).

The cells show a marked change of form during the growth cycle in complex media. Older cultures (about 3 to 7 d at 25 °C) are composed entirely or largely of coccoid cells which, on transfer to suitable fresh complex medium, grow out to give the slender irregular rods characteristic of exponential phase cultures. Many cells are arranged at an angle to each other to give V-formations; primary branching may occur. As growth proceeds, the rods become shorter and are eventually replaced by the coccoid cells (or short rods of occasional strains) characteristic of stationary phase cultures. Both rods and coccoid cells are Gram-positive, non-acid fast and non-motile; endospores are not formed. They are obligate aerobes, the mode of metabolism is respiratory, never fermentative; acids are not
Brevibacterium iodinum nom.rev.; comb.nov.

formed from glucose and other sugars in peptone media. They are catalase positive. The cell wall peptidoglycan is based on meso-diaminopimelic acid (variation A17); the cell walls do not contain arabinose. The bacteria contain dihydrogenated menaquinones with eight isoprene units, predominantly anteiso- and iso-methyl-branched fatty acids (anteiso C15 and anteiso C17) as major components, polar lipids comprising diphasphatidylglycerol, phosphatidylglycerol and dimannosyl diacylglycerol, but lack mycolic acids. The DNA base composition is in the range 60 to 64 mol % G+C.

The main distinguishing features between the genus Brevibacterium and other coryneform taxa are listed in Table 3. The type species is B. linens.

Emended description of Brevibacterium linens (Wolff) Breed

This description is based mainly on studies of the type strain ATCC 9172 (Skerman et al., 1980) and strains ATCC 9174 and NCIB 8546 (Fiedler et al., 1970; Schliefer & Kandler, 1972; Rogosa & Keddie, 1974; Jones, 1975; Keddie & Cure, 1977; Collins et al., 1979a; Keddie & Jones, 1980; the present work).

Surface colonies on nutrient agar are small (0.1 to 0.2 mm diam.) after 1 to 2 d, becoming larger (2-5 mm) on extended incubation; convex with entire margin, shiny; pale yellow to deep orange pigment produced. Pigment often produced only in the presence of light. Pigmented growth gives characteristic colour reactions with various acids and bases (Jones, 1975). Cultures on suitable media show the rod/coccus growth cycle and staining reactions described for the genus. Optimum growth temperature 20 to 25 °C; growth poor or absent at 5 and 37 °C. Salt tolerant, grows in the presence of NaCl (10%, w/v). Aerobic: mode of metabolism respiratory, never fermentative. Acids are not formed from glucose and other sugars in peptone media. Catalase positive, weakly oxidase positive. Gelatin liquefied, casein hydrolysed, hippurate hydrolysed, extracellular DNAase produced. The cell wall peptidoglycan contains meso-diaminopimelic acid (Fiedler et al., 1970); arabinose is not present but the wall polysaccharide contains a glycerol teichoic acid (Fiedler & Stackebrandt, 1978). Mycolic acids are not present (Goodfellow et al., 1976). The principal isoprenoid quinones are dihydrogenated menaquinones with eight isoprene units. The fatty acid composition is mainly anteiso- and iso-methyl-branched acids with small amounts of straight-chain acids. The major fatty acids are 14-methylhexadecanoic (anteiso C15) and 12-methyltetradecanoic (anteiso C13) acids. The polar lipids comprise diphasphatidylglycerol, phosphatidylglycerol and dimannosyl diacylglycerol. The G+C content of the DNA, determined by estimation of the melting point, is 60 to 64 mol % (Yamada & Komagata, 1970; Crombach, 1972; Bousfield, 1972).

Description of Brevibacterium iodinum nom.rev.; comb.nov.

This description is based on studies of strains NCDO 613, NCIB 8179, ATCC 15728, and ATCC 15729 (Clemo & Daglish, 1950; Gilman, 1953; Sneath, 1956, 1960; Steele, 1961; Colwell et al., 1969; Fiedler et al., 1970; Jones, 1975; the present work).

Surface colonies on nutrient agar are 0.75 to 1 mm diam. after 1 to 2 d, becoming larger (2 to 5 mm) on extended incubation; convex with entire margin, shiny. Blue to purple extracellular crystals of iodinin visible within 2 d in areas of heavy growth. Iodinin production not influenced by light but better production on certain media (Colwell et al., 1969). Colour reactions typical of B. linens growth absent (Jones, 1975). Cultures on suitable media show the rod/coccus growth cycle and staining reactions described for the genus (Fig. 3). Gram-positive, but may appear Gram-negative (Jones, 1975). In very young cultures (about 8 h) cells frequently stain one-half Gram-positive, the other Gram-negative (Colwell et al., 1969). Optimum growth temperature 25 °C; growth at 30 °C, but poor or absent at 5 and 37 °C. Aerobic: mode of metabolism respiratory. Acids not formed from glucose and other sugars in peptone media. Catalase positive, strongly oxidase
positive. Gelatin hydrolysed, extracellular DNAase produced, weak hydrolysis of casein, hippurate not hydrolysed (Jones, 1975). The cell wall peptidoglycan contains meso-diaminopimelic acid (Fiedler et al., 1970). Mycolic acids are not present. The principal isoprenoid quinones are dihydrogenated menaquinones with eight isoprene units. The fatty acid composition is mainly anteiso- and iso-methyl-branched acids with small amounts of straight-chain acids. The major fatty acids are 14-methylhexadecanoic (anteiso C\textsubscript{14}) and 12-methyltetradecanoic (anteiso C\textsubscript{12}). Diphosphatidylglycerol, phosphatidylglycerol and dimannosyl diacylglycerol comprise the polar lipids. The G+C content of the DNA, determined by estimation of the melting point is, 63 mol % (Colwell et al., 1969). The type strain is NCDO 613.
