The Degradation of p-Coumaryl Alcohol by *Aspergillus flavus*

By C. B. IYAYI† AND R. K. DART*

Microbiology Unit, Department of Chemistry, University of Technology, Loughborough, Leicestershire LE11 3TU, U.K.

(Received 21 September 1981; revised 2 November 1981)

*Aspergillus flavus* utilized p-coumaryl alcohol, one of the major constituents of lignin, as sole carbon source. The following compounds were isolated from the growth medium and identified by means of their melting points, IR, NMR and mass spectra: p-coumaric acid, p-hydroxybenzoic acid and protocatechuic acid. Culture filtrates from mycelium grown on p-[1-14C]coumaryl alcohol contained p-[14C]coumaric acid, β-hydroxy-(p-hydroxyphenyl)[14C]propionic acid, (p-hydroxybenzoyl)[14C]acetoacetic acid and [14C]acetic acid. Oxidation of protocatechuic acid by crude cell-free extracts formed β-ketoacidipic acid, which was isolated and characterized.

A pathway for the degradation of p-coumaryl alcohol by *Aspergillus flavus* is proposed.

**INTRODUCTION**

Lignin is one of the most important sources of renewable carbon in nature. Chemically, it is thought to be formed by the oxidative polymerization of the three substituted cinnamyl alcohols: p-coumaryl, coniferyl and sinapyl alcohols (Freudenberg & Neish, 1968; Higuchi, 1971; Kirk, 1971). The biodegradation of lignin in nature is carried out mainly by fungi, especially the 'wood rotting' fungi; several authors (Cowling, 1961; Oglesby *et al.*, 1967) have compiled extensive lists of such fungi. A few bacteria are also known to degrade lignin and lignin model compounds (Stanier & Ornston, 1973; Kawakami, 1976, 1980; Fukuzumi, 1980).

Studies on the microbial degradation of lignin have made use of a series of model compounds which circumvent some of the problems associated with the use of native lignin (Ander & Eriksson, 1978). The sequence of reactions leading from lignin to its monomers is controversial and the importance of monomers such as p-coumaryl alcohol in the degradation process is not fully understood.

*Aspergillus flavus* has been isolated from wood-rotting systems, and the metabolism of this organism is of considerable interest because of its ability to grow on a large variety of agricultural produce and synthesize a number of toxic compounds. This paper provides evidence for the degradation of p-coumaryl alcohol by *A. flavus*.

**METHODS**

*Maintenance and growth of A. flavus.* *Aspergillus flavus* CMI 15959 was obtained from the Commonwealth Mycological Institute, Ferry Lane, Kew, Surrey, U.K. It was maintained on slopes of the following medium: maltose, 38 g; yeast extract, 2.5 g; mycological peptone, 8 g; malt extract, 2 g; agar, 20 g; water to 1 l; pH 5.0. It was subcultured at intervals of 2 weeks.

The fungus was grown in a medium comprising: NaNO₃, 5 g; KH₂PO₄, 5 g; Bacto-yeast extract, 0.1 g; the appropriate carbon source at 6–25 × 10⁻³ m; water to 1 l. The pH was adjusted to 5.2 with 1 m-NaOH and medium dispensed in 100 ml portions in 1 l Erlenmeyer flasks.

† Present address: Department of Biochemistry, University of Benin, Benin City, Nigeria.
Cultures required for quantitative growth experiments were inoculated with 1 ml of spore suspensions containing approximately 10^5 spores which had been prepared and harvested by the method of Dart (1975).

Cultures were incubated at 30 °C under static conditions or shaken on an orbital incubator at 100 rev. min⁻¹ at 30 °C for 7 d unless otherwise stated.

Cultures were harvested by filtration when grown statically and by centrifugation when shake cultures were used for manometric studies. Quantitative growth measurements were made by dry weight determinations.

**Cell-free extracts.** Mycelial mats were harvested by filtration, washed twice with buffer and macerated by hand for 5 min with an equal weight of alumina beads in a chilled mortar. Sodium phosphate buffer (0-025 M) pH 7-0 was added and the mixture homogenized and centrifuged at 15000 g for 30 min. The supernatant obtained was decanted and used immediately.

**Protein determination.** Protein was estimated by the method of Stickland (1951), using bovine serum albumin as standard.

**Manometry.** The oxygen consumption of both mycelial mats and cell-free extracts was determined using a Warburg apparatus (Umbreit et al., 1964) supplied by Braun (F. T. Scientific Instruments, Tewkesbury, U.K.).

The temperature of incubation was 30 °C and the gas phase was air. The total volume of liquid in the flasks was 3 ml made up as follows. The main chamber contained 1-8 ml mycelial suspension or mycelial extract (approx. 10 mg protein) suspended in 0-5 M-phosphate buffer pH 5-2. The centre well contained 0-2 ml 20% (w/v) KOH and a small piece of filter paper. The reaction was started by tipping 1-0 ml substrate (5 μmol) from the side arm into the main compartment. Readings were taken at 10 min intervals.

**Chemicals.** The synthesis of p-coumaryl alcohol was carried out from p-coumaric acid by the method of Li & Elliot (1952). The method of Hauser & Breslow (1955) was used to synthesize β-hydroxy(p-hydroxyphenyl)propionic acid from p-hydroxybenzaldehyde and the product oxidized to form (p-hydroxybenzoyl)acetic acid using acidified KMnO₄. The synthesis of β-[1-¹⁴C]coumaric acid from p-hydroxybenzaldehyde and sodium [¹⁴C]cyanide was carried out by the method of Lapworth & McRae (1922) and p-[1-¹⁴C]coumaryl alcohol was synthesized from p-[1-¹⁴C]coumaric acid by the method of Allen & Byers (1949).

In all cases the purity of the synthesized compounds was checked by chromatography and spectral analysis.

The method of Riegel & Lilienfeld (1945) was used to synthesize β-ketoacidic acid and its purity checked by melting point determination (119-121 °C, literature value 122 °C) and ascending paper chromatography of the 2,4-dinitrophenylhydrazone derivative. The solvents were 2-methylbutan-2-ol/propan-2-ol/ammonia (sp.gr. 0.88) (13:1:6, by vol.) for the first direction and propan-2-ol/ammonia (sp.gr. 0.88)/water (20:1:2, by vol.) for the second direction. Spots were detected by spraying with 0-1 M-NaOH.

**Isolation of intermediates.** The fungus was grown on 250 ml medium containing p-coumaryl alcohol (6-25 × 10⁻³ M) in a 1 l Erlemeyer flask under static conditions at 30 °C. The mycelial mat was harvested by filtration, washed with distilled water and used to inoculate 250 ml fresh medium pH 5-2, containing p-coumaryl alcohol or one of the postulated intermediates, each at 1 mg ml⁻¹. After incubation for 6 h at 30 °C on an orbital shaker operating at 100 rev. min⁻¹, the fungal mat was removed by filtration and washed twice with distilled water. The volume of the combined filtrate and washings was reduced to approximately 30 ml by freeze drying, acidified to pH 2-0 with 2 M-HCl and extracted three times with diethyl ether. After combining and drying the ether extracts over anhydrous Na₂SO₄, the organic phase was evaporated to dryness. The residue was dissolved in ethanol and chromatographed by fractionation.

**Isolation of radioactive intermediates.** A 7 d old mycelial mat was harvested by filtration, washed with distilled water and resuspended in 10 ml fresh medium. p-[1-¹⁴C]Coumaryl alcohol (2 μCi, 100 μmol) was added and incubated at 30 °C on an orbital incubator (100 rev. min⁻¹). At various time intervals portions of medium were removed, added to hot methanol (2 ml) and the precipitate formed was removed by centrifuging and washed with methanol. The methanolic samples were pooled, dried, acidified to pH 2-0 with 2 M-HCl and extracted with diethyl ether.

The ethereal extracts were spotted on to triplicate paper chromatograms. One paper was visualized by spraying as described below and the position of the spots on the second paper checked using a strip scanner. The spots were eluted with 2 M-NaOH, acidified with 2 M-HCl and extracted three times with diethyl ether before drying and counting in a scintillation counter. The identity of the compound was checked by elution from the third chromatograph, mixing portions of the sample with possible intermediates followed by co-chromatography. The melting point was then determined and checked against an authentic sample.

**Chromatography.** Thin-layer chromatography was carried out on silica gel G using a solvent of benzene/acetic acid (9:1, by vol.) (Smith, 1960). Two-way paper chromatography was carried out on Whatman no. 1 paper using the solvent system of Reio (1958). Chromatograms were viewed under UV light to visualize aromatic intermediates. Phenolic compounds were detected as described by Smith (1960), carboxylic acids were detected by spraying with KMnO₄ and carbonyl compounds were sprayed with a saturated solution of alkaline 2,4-dinitrophenylhydrazine.

The various intermediates separated by thin-layer chromatography were eluted with NaOH and the eluates acidified and extracted with diethyl ether. The compounds were purified by thin-layer chromatography, eluted with alkali, acidified, extracted with diethyl ether, dried and recrystallized from hot water.
p-Coumaryl alcohol metabolism by Aspergillus

Identification of compounds. The melting points of compounds which had been purified by chromatography and recrystallization were obtained separately and also mixed with authentic samples. IR spectra were obtained on a Perkin-Elmer SP2000 from samples dissolved in nujol. UV spectra were obtained on a Unicam SP800 recording spectrophotometer from samples dissolved in UV ethanol. Mass spectra were obtained using an AEI MS312 spectrophotometer and NMR spectra were obtained on a Perkin-Elmer R32 from samples dissolved in CDCl₃.

Isolation of β-ketoadipic acid. Crude cell-free extracts (approx. 150 mg protein) were prepared in 300 ml 0.1 M-sodium phosphate buffer pH 7.0 and stirred at 30 °C. Protocatechuic acid (3 mmol) was added in 50 μmol aliquots and samples were then removed and tested for residual protocatechuic acid (Evans, 1947). Incubation was continued for 2 h after a negative test for protocatechuic acid was obtained.

The product was isolated by the method of Darrah & Cain (1967), subjected to a Rothera test (Rothera, 1908) and the melting point determined. The 2,4-dinitrophenylhydrazone derivative was prepared and co-chromatographed with the 2,4-dinitrophenylhydrazone of an authentic sample of β-ketoadipic acid using a solvent consisting of 2-methylbutan-2-ol/propan-2-ol/ammonia (sp.gr. 0.88) (13:6:1, by vol.) on Whatman no. 1 paper. Spots were detected by spraying with 0.1 M-NaOH.

The spectral properties of the isolates were compared with those of authentic β-ketoadipic acid and the product was estimated by the method of Sistrom & Stanier (1953).

Identification of [14C]lactic acid. Biogel P10 was suspended in 0.1 M-phosphate buffer pH 7.0 and allowed to stand for 1 h before packing a column (32 × 2 cm). The eluant used was 0.01 M-HCl and samples (2 ml) were adjusted to pH 7.0 with 0.1 M-NaOH before application to the column.

The column was calibrated with p-coumaric acid which was detected in the fractions (5 ml) spectrophotometrically at 310 nm. Maximum elution of acid occurred in fractions 36 and 37. The column was also calibrated with [1-14C]lactic acid (10 mg, 0.1 μCi) adjusted to pH 7.0 with 0.1 M-NaOH, using the same eluant. Maximum elution of [1-14C]lactic acid occurred in fractions 27–29.

Samples consisting of 50 μmol p-[1-14C]coumaric acid in 15 ml 0.025 M-phosphate buffer pH 7.0 were oxidized by cell-free extracts (approx. 150 mg protein) for 1 h at 30 °C in the presence of 1.0 μmol NAD⁺. The reaction was stopped by adding 2 M-HCl to pH 2.0 and the mixture was extracted twice with diethyl ether. The ethereal extracts were pooled, dried, redissolved in 0.1 M-NaOH and the pH was adjusted to 7.0 with 0.01 M-HCl. Samples (2 ml) were applied to the column and eluted with 0.01 M-HCl.

Fractions containing acetic acid were pooled, adjusted to pH 7.0 with 0.1 M-NaOH and freeze dried. Acetate was detected and characterized by two-dimensional paper chromatography using ethanol/ammonia (sp.gr. 0.88)/water (20:1:4, by vol.) and propan-2-ol/ammonia (sp.gr. 0.88)/water (20:1:2, by vol.) and detected by spraying with bromocresol purple.

Determination of 14CO₂. Radioactive CO₂ evolved from p-[1-14C]coumaric acid was determined by the method of Perrin & Towers (1973). Filtered air was passed through 20% KOH to remove the CO₂ and then passed through a wash bottle containing sterile water. The CO₂-free air was bubbled into a flask containing mycelium removed from 25 ml culture and resuspended in 25 ml phosphate buffer pH 5.2 containing 10 μmol p-[1-14C]coumaric acid. After passage through the culture the air was passed through 10 ml methanolic Hyamine hydroxide. Aliquots of this were removed at intervals and counted in a scintillation counter.

Enzyme assays. The NAD⁺-linked β-hydroxy-(p-hydroxyphenyl)propionic acid dehydrogenase of the crude cell-free extract was assayed at 30 °C by measuring the increase in absorbance at 340 nm. The reaction mixture consisted of β-hydroxy-(p-hydroxyphenyl)propionic acid (10 μmol), NAD⁺ (1 μmol), crude cell-free extract (1 ml; approx. 10 mg protein) and sodium phosphate buffer (pH 8.5, 0.1 M) to give a final volume of 3 ml. At the end of the reaction the samples were pooled and treated with an acidic solution of saturated 2,4-dinitrophenyldiazine. The brown precipitate obtained was filtered and dried, and its melting point determined both separately and mixed with an authentic sample of the 2,4-dinitrophenyldiazine derivative of authentic (p-hydroxybenzoyl)acetic acid. The sample was also subjected to chromatography and compared with the authentic 2,4-dinitrophenyldiazine.

RESULTS

Growth experiments. Glucose (6.25 × 10⁻³ M) was a better carbon source for growth of A. flavus than p-coumaryl alcohol at the same concentration (Fig. 1).

Identification of intermediates. When mycelial mats were suspended in fresh medium containing p-coumaryl alcohol and incubated for 6 h, four aromatic compounds were obtained (Table 1). Fewer aromatic compounds were isolated when p-coumaryl alcohol was replaced by postulated intermediates as sole carbon source (Table 2). The incubation of boiled mycelium with p-hydroxybenzoic acid gave small amounts of p-hydroxybenzaldehyde.

Manometric studies. A number of postulated intermediates were oxidized by both whole mycelium and cell-free extracts. These included p-coumaric acid, p-hydroxybenzoic acid and...

*Corrected for background.

Radioactive labelling. When *A. flavus* was fed with 2 μCi p-[1-14C]coumaryl alcohol, the only radioactively labelled metabolite which could be isolated was p-coumaric acid (Table 3). Incubation of p-[1-14C]coumaric acid with intact mycelium resulted in the evolution of 14CO2 after a lag phase of approximately 20 min.

Incubation of the labelled compound with cell-free extracts in the presence of NAD⁺ gave rise to [14C]acetate which was confirmed by chromatographic analysis (see Methods).

Rapid sampling experiments using p-[1-14C]coumaryl alcohol produced two transient radioactively labelled intermediates in amounts too small for analysis. Two possible
Fig. 4. Rapid sampling of A. flavus utilizing p-coumaryl alcohol. Mycelium from cultures 7 d old was suspended in 10 ml fresh medium containing 100 μmol p-coumaryl alcohol. Unlabelled β-hydroxy-(p-hydroxyphenyl)propionic acid and (p-hydroxybenzoyl)acetic acid were added, followed by 1 μCi p-[1-14C]coumaryl alcohol; 1 ml samples were removed at 10 s intervals and added to 2.0 ml boiling methanol. The precipitate was removed by centrifuging and the methanolic samples dried and chromatographed. Samples were purified to constant activity and then counted by scintillation counting. ●, p-[14C]Coumaric acid; ○, β-hydroxy-(p-hydroxyphenyl)[14C]propionic acid; □, (p-hydroxybenzoyl)[14C]acetic acid.

Fig. 5. Synthesis of protocatechuic acid. Mycelium from cultures 7 d old was resuspended in 100 ml fresh medium containing either 100 mg p-coumaric acid (a) or 100 mg p-hydroxybenzoic acid (b) and incubated for 24 h at 30 °C. Samples (10 ml) were removed at intervals and extracted with diethyl ether. They were dried, resuspended in methanol and chromatographed in a solvent of formic acid/water (1:49, by vol.). After separation the compounds were assayed spectrophotometrically, p-hydroxybenzoic acid (●) at 258 nm, p-coumaric acid (○) at 310 nm and protocatechuic acid (□) at 260 nm.

Intermediates are β-hydroxy-(p-hydroxyphenyl)propionic acid and (p-hydroxybenzoyl)acetic acid. These compounds were synthesized, their purity checked and 10 μmol each added to a mycelial suspension utilizing p-[1-14C]coumaryl alcohol. The β-hydroxy-(p-hydroxyphenyl)propionic acid and (p-hydroxybenzoyl)acetic acid were then reisolated and purified to constant activity by recrystallization. The appearance of radioactive label in these two compounds over a period of time was determined (Fig. 4).

**Synthesis of protocatechuic acid.** As the levels of p-hydroxybenzoic acid and p-coumaric acid fell, protocatechuic acid was synthesized by a mycelial suspension (Fig. 5a, b). The enzyme p-hydroxybenzoate hydroxylase was not assayed in cell-free extracts.
Enzyme assay. Crude cell-free extracts of *A. flavus* showed NAD⁺-linked dehydrogenase activity when β-hydroxy-(p-hydroxyphenyl)propionic acid was used as substrate. No activity could be demonstrated when NADP⁺ was added instead of NAD⁺. When the final products of a number of these assays were mixed and treated with an acidic solution of saturated 2,4-dinitrophenyldrazine, a 2,4-dinitrophenyldrazone was formed which had the same melting point and chromatographic properties as that of the 2,4-dinitrophenyldrazone of an authentic sample of (p-hydroxybenzoyl)acetic acid (100–102°C).

It was not possible to identify ring cleavage products in any of the whole cell experiments. However, a Warburg experiment utilizing cell-free extracts in the presence of protocatechuic acid showed oxygen uptake (Fig. 3). The size of the experiments was increased, and when cell-free extracts were incubated with 3 mmol protocatechuic acid, approximately 100 mg of a compound which was identified as β-ketoadipic acid by a positive Rothera test was isolated. Melting point determinations of the isolate (117 °C) compared with that of an authentic sample (118 °C) and of the 2,4-dinitrophenyldrazone (206 °C) compared with the 2,4-dinitrophenyldrazone of an authentic sample (206 °C) confirmed its identity. The IR spectrum of the isolated compound was also compatible with its identification as β-ketoadipic acid.

An assay of the β-ketoadipic acid and carbon dioxide formed from protocatechuic acid by cell-free extracts showed that the reaction was nearly stoichiometric. Every mole of protocatechuic acid disappearing resulted in the production of 0.96 mol β-ketoadipic acid and 1.01 mol carbon dioxide.

**DISCUSSION**

The initial step in the degradation of *p*-coumaryl alcohol involves its conversion to the corresponding carboxylic acid. Several authors have shown that this takes place via the aldehyde (Sundman, 1964; Liu & Johnson, 1971; Ratledge, 1978). The free aldehyde (p-hydroxycinnamyl aldehyde) could not be detected in this study although labelled *p*-coumaric acid could be isolated after incubation of the cells with labelled *p*-coumaryl alcohol.

The further conversion of *p*-coumaric acid to *p*-hydroxybenzoic acid could take place by one of two pathways. Several authors have reported that cinnamic acid and related compounds could be converted to the corresponding benzoic acid derivative by a process of β-oxidation (Henderson & Farmer, 1955; Henderson, 1961; Zenk & Muller, 1964; Vollmer et al., 1965). Other workers, however, have reported the non-oxidative shortening of the side chain of such compounds to give the corresponding benzaldehyde derivative which could then be oxidized to the corresponding acid (Toms & Wood, 1970; Kindl & Ruis, 1971; French et al., 1976). This pathway would not involve the formation of coenzyme A derivatives. A requirement for coenzyme A derivatives could not be demonstrated during the metabolism of the side chain of *p*-coumaryl alcohol by *Aspergillus flavus*.

The formation of [14C]acetate during the degradation of *p*-1-[14C]coumaric acid gives no indication which of these pathways is operating as they would both give rise to [14C]acetate. Both *p*-hydroxybenzaldehyde and *p*-hydroxybenzoic acid could be isolated after cells had been incubated with *p*-coumaric acid, although only trace amounts of *p*-hydroxybenzaldehyde were found. However, *p*-hydroxybenzaldehyde could be isolated when boiled cells were incubated with *p*-hydroxybenzoic acid. Only *p*-14C]coumaric acid and not *p*-hydroxy[14C]benzoic acid or [14C]protocatechuic acid could be isolated and identified after incubation with *p*-14C]coumaryl alcohol. This is explained by the 14C of the side chain being removed as [14C]acetate (Fig. 6).

During rapid sampling experiments, small amounts of two radioactively labelled compounds were obtained which were identified as β-hydroxy-(p-hydroxyphenyl)propionic acid and (p-hydroxybenzoyl)acetic acid. Both of these compounds would be formed during a
\( \text{\( \beta \)-oxidation but only \( \beta \)-hydroxy-}\((p\)-hydroxyphenyl)propionic acid would be formed in the non-oxidative pathway of the type proposed by Toms & Wood (1970). In addition the NAD\(^+\)-linked dehydrogenase converting \( \beta \)-hydroxy-\((p\)-hydroxyphenyl)propionic acid to \((p\)-hydroxybenzoyl)acetic acid could be demonstrated in cell-free extracts. This enzyme would not be required in the non-oxidative pathway but carries out an essential step in \( \beta \)-oxidation. The evidence therefore suggests that \( p \)-hydroxybenzaldehyde arises from \( p \)-hydroxybenzoic acid as an artefact of isolation and chromatography, and the conversion of \( p \)-coumaric acid to \( p \)-hydroxybenzoic acid involves a \( \beta \)-oxidation type of reaction.}

Incubation of \( p \)-\([1-^{14}\text{C}]\)coumaric acid with intact mycelium produced \(^{14}\text{CO}_2\) after a lag phase of approximately 20 min, which is presumed to be the time required to convert \([^{14}\text{C}]\)acetate to \(^{14}\text{CO}_2\).

The enzyme \( p \)-hydroxybenzoate hydroxylase was not demonstrated in \( A. \text{\textit{flavus}} \) grown on \( p \)-coumaryl alcohol but we have shown the presence of this enzyme and its inducible nature in \( A. \text{\textit{flavus}} \) grown on mandelic acid (unpublished results).

The results show that protocatechuic acid was synthesized when \( p \)-coumaric acid and \( p \)-hydroxybenzoic acid were metabolized by intact mycelium. Protocatechuic acid was also
metabolized without a lag phase by both whole cells and cell-free extracts, whereas catechol was only metabolized slowly. Protocatechuic acid is the last aromatic compound in the metabolic sequence and ortho or intradiol cleavage by the enzyme protocatechuic acid 3,4-dioxygenase would ultimately give rise to β-ketoacidic acid. The various intermediates (Cain et al., 1968) were not isolated but β-ketoacidic acid could be purified and identified from the reaction mixture. The pathway of degradation of p-coumaryl alcohol as shown in Fig. 6 is therefore proposed.

One feature which has not yet been investigated is the low mycelial yield on p-coumaryl alcohol (Fig. 1). An examination of the theoretical yield of ATP from p-coumaryl alcohol suggests that the cell yield should be somewhat higher than that from glucose. Several explanations are possible and these are being investigated further.
