(Received 7 February 1983; revised 13 May 1983)

Propionibacterium acnes, Propionibacterium avidum and Propionibacterium granulosum were grown in continuous culture at 0–100% air saturation using a semi-synthetic medium. Maximum specific growth rate, biomass concentration and extracellular lipase, hyaluronate lyase and phosphatase activities were determined. All three species were capable of growth at 100% air saturation but at reduced growth rates. The presence of oxygen altered the production of extracellular enzymes. Propionibacterium avidum was the best adapted for growth in aerobic environments.

INTRODUCTION

Propionibacterium acnes constitutes the major fraction of the microflora in areas of adult human skin rich in sebaceous glands, i.e. face, back and chest (Johnson & Cummins, 1972; McGinley et al., 1978). Propionibacterium granulosum and Propionibacterium avidum are isolated from these areas in lesser numbers (McGinley et al., 1978). Propionibacterium avidum also colonizes skin of high humidity, i.e. axilla and groin (McGinley et al., 1978). Propionibacteria can be isolated both from the skin surface and from the pilosebaceous ducts (Puhvel et al., 1975). They produce a variety of extracellular enzymes including lipase (Hassing, 1971; Kellum et al., 1970; Ingham et al., 1981; Greenman et al., 1981), hyaluronidase (hyaluronidase lyase) (Puhvel & Reisner, 1972; Ingham et al., 1979; Greenman et al., 1981), protease and DNAase (Marple & McGinley, 1974) and acid phosphatase (Ingham et al., 1980; Greenman et al., 1981). Holland et al. (1978) suggested that altered conditions in the pilosebaceous duct, i.e. pH or oxygen concentration, effect changes in the physiology of the resident bacteria and in the synthesis of extracellular products.

The cutaneous propionibacteria are generally regarded as anaerobes since they normally require anaerobiosis for their isolation and growth (Evans et al., 1950). However, these bacteria can also be isolated aerobically (Evans & Mattern, 1979). It is also likely that they are exposed to oxygen in their natural environment due to diffusion both from the tissues and the atmosphere. The aim of this study was to determine the effects of oxygen on the growth and production of extracellular enzymes by cutaneous propionibacteria.

METHODS

Organism and media. Propionibacterium acnes [laboratory strain P37], P. avidum [laboratory strain PF77 (i)] and P. granulosum [laboratory strain PF208 (ii)] were originally isolated from patients attending the Dermatology clinic at Leeds General Infirmary and were typed according to the scheme of Marples & McGinley (1974). The strains were maintained at −196 °C under liquid nitrogen. The growth medium was that used by Eaves et al. (1979).

The medium used for the growth of *P. granulosum* contained glucose (2 g l\(^{-1}\)), since this species has been shown to require a carbohydrate carbon source (Holland *et al.*, 1979; Greenman *et al.*, 1981). The medium was autoclaved at 121 °C for 80 min in 20 l amounts; the vitamins, mineral salts and glucose (10%, w/v) were autoclaved separately at 121 °C for 15 min, cooled and added aseptically to the rest of the medium.

**Continuous culture apparatus and conditions.** Organisms were grown in a 1 litre culture vessel (working volume 750 ml) with control modules for temperature, stirrer, gas flow, pH and dissolved oxygen concentration (Series 1500, LH Engineering, Stoke Poges, Bucks., U.K.). The cultures were maintained at 37 °C and at pH 5.7 by the automatic addition of 2 M-NaOH or 2 M-HCl, and were stirred at 500 r.p.m. Percentage oxygen saturation in the culture was measured using a galvanic oxygen electrode supplied by L. H. Engineering, Stoke Poges, Bucks., U.K. The electrode was calibrated at zero and 100% saturation by sparging oxygen-free nitrogen at 100 ml min\(^{-1}\) and air at 300 ml min\(^{-1}\), respectively. Hence, 100% saturation in the culture is with reference to the partial pressure of oxygen in air. The oxygen saturation in the culture was controlled automatically using a gas mixture of oxygen-free nitrogen and air. The pH and oxygen saturation were chart recorded (Foster Cambridge Ltd). Foaming was controlled by the addition of polypropylene glycol antifoam (BDH) where necessary. The dilution rates were maintained at one-third of the maximum specific growth rate of the organism under the conditions imposed. Samples were taken at regular intervals for microscopical examination and for plating on to Reinforced Clostridial Medium (Oxoid), which was incubated anaerobically in H\(_2\)-CO\(_2\) (95:5, v/v) at 37 °C for 5 d, and on 5% (w/v) heated horse blood agar (Oxoid), which was incubated aerobically for 2 d at 37 °C, to test for purity.

**Determination of biomass and maximum specific growth rates.** Bacterial dry weight was used as a measure of the biomass and was determined by the method of Greenman *et al.* (1981). The absorbance at 540 nm was used to measure bacterial concentration for determination of maximum specific growth rate. The maximum specific growth rate \((\mu_{\text{max}})\) was determined by the 'washout method' of Tempest (1970). The dilution rate was raised to near \(\mu_{\text{max}}\), 48 h before it was raised above \(\mu_{\text{max}}\). The values of \(D\) above \(\mu_{\text{max}}\) are given in Table 1.

**Total and viable bacterial counts.** Total counts were measured using a Helber counting chamber and phase-contrast microscopy and viable counts were determined using conventional plating techniques.

**Extracellular protein.** Protein in the medium was determined by the method of Bradford (1976) using the procedure and reagents described in the Bio-Rad Laboratories technical bulletin 1051E. The results were expressed as bovine serum albumin (g l\(^{-1}\)) equivalent and the production rate of extracellular protein was calculated as g l\(^{-1}\) h\(^{-1}\).

**Extracellular enzymes.** Lipase (EC 3.1.1.3), hyaluronate lyase (EC 4.2.2.1) and acid phosphatase (EC 3.1.3.2) activities were assayed by the methods used by Holland *et al.* (1979). Enzyme units of activity were expressed as \(\mu\)mol end product produced min\(^{-1}\) as follows: lipase, \(\mu\)mol oleic acid min\(^{-1}\); hyaluronidase, \(\mu\)mol N-acetylglucosamine min\(^{-1}\) and phosphatase \(\mu\)mol p-nitrophenol min\(^{-1}\). The production rates of extracellular enzymes were expressed as units of activity (g biomass)\(^{-1}\) h\(^{-1}\) (Pirt, 1975).

**Stability of extracellular enzymes.** The stability of extracellular enzymes was determined anaerobically and at 100% air saturation using the method described by Eaves *et al.* (1979). The production rates were corrected for loss of enzyme activity due to instability using the formula:

\[
\text{corrected activity} = [(\lambda + D)/D] \times \text{measured activity}
\]

where \(D\) is the dilution rate and \(\lambda\) is the denaturation constant for the enzyme (Eaves *et al.*, 1979).

**Glucose.** The glucose concentration in cultures of *P. granulosum* was determined according to Sigma technical bulletin no. 510.

**Phosphorus.** Inorganic phosphate in the medium was determined according to Sigma technical bulletin no. 670.

**N-acetylglucosamine.** Culture supernatant fluids were assayed for *N*-acetylglucosamine using the colorimetric assay of Reissig *et al.* (1955).

**Steady state.** Biomass and extracellular enzyme activities were determined on samples taken from the chemostat conditions.
Oxygen and skin propionibacteria

Fig. 1. Effect of oxygen concentration on the maximum specific growth rate of *P. acnes* (○), *P. granulosum* (●) and *P. avidum* (□).

Fig. 2. Effect of oxygen concentration on biomass production rate at 0.33 μmax of *P. acnes* (○), *P. granulosum* (●) and *P. avidum* (□). Biomass production rate is expressed as g l⁻¹ h⁻¹. Each point and bar indicates the mean ± 95% confidence limits.

during the particular conditions of oxygen concentration that were selected. Only after a minimum of six culture volume changes (typically ten) had occurred between particular conditions was a steady state condition considered to have been achieved. Samples of culture supernatant fluids from steady states were stored at -20°C for later analysis of inorganic phosphate, glucose, N-acetylglucosamine and extracellular protein.

The cultures were grown anaerobically under batch culture prior to each continuous culture experiment to minimize the selective pressure for mutants with increased oxygen tolerance.

**Statistical analysis.** For biomass and extracellular enzyme production data 95% confidence limits were calculated.

**RESULTS**

Maximum specific growth rate, biomass, viable and total counts, extracellular protein and extracellular enzyme production were measured for each species of *Propionibacterium* grown at steady state with air saturation from 0 to 100%. Steady states were obtained for all three species of cutaneous propionibacteria over the range of 0 to 100% air saturation.

**Maximum specific growth rate.** Values of μmax obtained by the ‘washout’ method are shown in Fig. 1. The μmax obtained for the anaerobic growth of *P. acnes* was 0.195 h⁻¹, for *P. avidum* 0.195 h⁻¹, and for *P. granulosum* 0.120 h⁻¹. These results were in close agreement with those obtained by Greenman *et al.* (1983) at pH values 5.5 and 6.0. The presence of oxygen reduced the μmax of all three species of propionibacteria. This effect was most apparent with *P. acnes* when the oxygen concentration was increased from 0 to 20% air saturation. *Propionibacterium avidum* maintained the highest growth rates in the presence of oxygen. The μmax of *P. granulosum* was reduced from 0.082 h⁻¹ to 0.02 h⁻¹ when the oxygen concentration was increased from 80 to 100% air saturation.

**Biomass.** Biomass (g l⁻¹) increased for all three species between 0 and 20% air saturation and at 100% for *P. granulosum*. However, the production rate of biomass assessed as g l⁻¹ h⁻¹ showed an overall gradual downward trend between 0 and 100% air saturation for *P. granulosum* (Fig. 2), a decrease between 0 and 20% saturation and no further change at higher air saturations for *P. acnes* whilst there was a peak of production at 10% air saturation for *P. avidum*. 
Fig. 3. Effect of oxygen concentration on extracellular protein production rate at 0.33 μₘₐₓ of P. acnes (○), P. granulosum (●) and P. avidum (□). Each point is the mean of duplicate determinations from a sample of culture supernatant fluid stored at -20 °C.

Table 2. Denaturation constants for the extracellular enzyme of P. acnes, P. avidum and P. granulosum determined under anaerobic and aerobic conditions

Denaturation constants were determined by the method of Eaves et al. (1979). Linear regression analysis was used to determine the slopes of the inactivation curves. The gradients obtained for each enzyme under anaerobic and aerobic conditions were compared using the F test. There was no significant difference (P > 0.05) between the values of λ obtained anaerobically and aerobically for any of the enzymes.

Total and viable bacterial counts. There was no detectable difference between the total and viable counts of propionibacteria growing at oxygen concentrations from 0 to 100% air saturation.

Extracellular protein. The method used to measure protein was insensitive to low molecular weight peptides and free amino acids in the tryptone. No detectable protein was found in tryptone using the Bio-Rad assay. These measurements therefore reflected the total extracellular protein production by the bacteria. This varied in all three species with oxygen concentration (Fig. 3). The highest rate of extracellular protein production was achieved by P. acnes growing at 0% air saturation.

Extracellular enzyme production. The stability constants for the propionibacterial extracellular enzymes determined under anaerobic conditions and at 100% air saturation are given in Table 2. Linear regression analysis was used to determine the slopes (λ) of the inactivation curves. The gradients obtained under anaerobic conditions were compared using the F test. There was no significant difference (P > 0.05) between the values of λ obtained anaerobically and
Oxygen and skin propionibacteria

Fig. 4. Effect of oxygen concentration on production rate of lipase at 0.33 μmax by P. acnes, uncorrected (○), P. granulosum, uncorrected (●) and P. avidum, uncorrected (□) and corrected (■) for enzyme denaturation. Lipase production rate is expressed as units of enzyme activity (g dry wt cells)⁻¹ h⁻¹. The other details are as in Fig. 2.

Fig. 5. Effect of oxygen concentration on the production rate of hyaluronate lyase at 0.33 μmax by P. acnes uncorrected (○) and corrected (●) and P. granulosum (□) uncorrected for enzyme denaturation. Hyaluronate lyase production rate is expressed as units of enzyme activity (g dry wt cells)⁻¹ h⁻¹. The other details are as in Fig. 2.

aerobically. It was therefore not considered necessary to determine λ for each enzyme at each oxygen concentration tested. The corrected values of extracellular enzyme production rates were calculated using the stability constant λ obtained anaerobically.

The results for the corrected and uncorrected production rates for the extracellular enzymes are given in Figs 4 to 6. The corrected anaerobic production rate of P. acnes lipase was 0.2 ± 0.08 units (g biomass)⁻¹ h⁻¹. Values for aerobic production rate of P. acnes lipase were not calculated since the levels of enzyme activity obtained were at the limit of detection of the assay, or zero. Corrected P. granulosum lipase and hyaluronate lyase production rates are not shown since the value of λ was zero for these enzymes. The uncorrected anaerobic production rate of lipase was highest by P. granulosum followed by P. avidum and P. acnes (Fig. 4). These findings were consistent with those of Greenman et al. (1983). The level of lipase production was reduced markedly by P. acnes and P. granulosum in the presence of oxygen. The corrected and uncorrected production of lipase by P. avidum remained constant throughout all the conditions of oxygen tested.

Hyaluronate lyase was produced only by the P. acnes and P. granulosum strains (Fig. 5). The highest rates of production were obtained at 20% air saturation for P. acnes and at 30% air saturation for P. granulosum. N-acetylglucosamine was detected in culture supernatant fluids of P. acnes. N-acetylglucosamine was not detected in culture supernatant fluids of P. granulosum or P. avidum.
Extracellular acid phosphatase was detected only in the *P. acnes* strains (Fig. 6). The rate of extracellular acid phosphatase production was reduced at all oxygen concentrations tested (Fig. 6). Analysis of culture supernatant fluids revealed that the growth of all three species of propionibacteria caused a release of inorganic phosphate into the medium from the tryptone-bound phosphate. The level of inorganic phosphate in *P. acnes* cultures appeared to be independent of the activity of extracellular phosphatase.

Corrected values for the production rates of *P. acnes* hyaluronate lyase and phosphatase were obtained which were significantly higher than the uncorrected data. This was apparent particularly at oxygen concentrations less than 40% air saturation.

**Glucose.** The glucose, present only in the medium of *P. granulosum* was completely utilized at all the steady states.

**DISCUSSION**

Continuous culture provides the most controlled method for determining the effects of environmental change on bacterial growth and product formation. In a tryptone-based medium, increase in glucose concentration up to 3% (w/v) increased the biomass of *P. acnes*, *P. avidum* and *P. granulosum* although only *P. granulosum* has a requirement for glucose (Greenman *et al.*, 1981). In the absence of glucose, cultures are, therefore, limited by amino acids supplied by the tryptone which act as both nitrogen and carbon-energy sources (Holland *et al.*, 1979; Greenman *et al.*, 1981). Addition of 0.2% (w/v) glucose to *P. granulosum* cultures merely spares amino acids that would otherwise be used as carbon-energy sources.

The bacteria were grown anaerobically between steady states to reduce the selection of strains with increased oxygen tolerance. Mutant strains were not detected using the aerobic purity check plates. It is therefore likely that the results obtained represent the phenotypic response of these bacteria to change in oxygen tension.

This study showed that the three species of cutaneous propionibacteria were capable of growth and extracellular enzyme production in the presence of oxygen. Measurements of total and viable counts indicated that oxygen was not lethal to these organisms. This finding was not unexpected since although anaerobiosis is usually required for their isolation and growth, cutaneous propionibacteria do not require anaerobic handling techniques and cultures remain viable when exposed to the atmosphere.
Propionibacterium avidum was the best adapted of the three species to aerobic environments with respect to growth rate and the production of biomass. Using these criteria, the term microaerophilic may be applied to P. avidum. It is interesting that this species is also the most nutritionally adaptable of the cutaneous propionibacteria (Ferguson & Cummins, 1978; Holland et al., 1979).

The most marked effect of oxygen on the cutaneous propionibacteria was a reduction in the maximum specific growth rate, which may explain the difficulty of isolating these organisms aerobically, since relatively slow growth rates are achieved under optimal conditions anaerobically (0.195 h⁻¹) and 5–7 d are required for their anaerobic isolation. The experiments were carried out at a fixed fraction 0.33 of the maximum specific growth rate of the organism under the conditions imposed. This enabled comparison of the performance of the three species at different percentage air saturation (Tempest, 1976). Since oxygen reduced $\mu_{\text{max}}$, the production rates of cells and extracellular enzymes were consequently affected.

Oxygen did not affect the stability of the propionibacterial extracellular enzymes, but the residence time for each steady state ($D = 0.33 \mu_{\text{max}}$) was different since $\mu_{\text{max}}$ varied with oxygen concentration. The enzymes were therefore subject to different times of denaturation in the fermenter at different steady states. The derivation of corrected production rates allowed valid comparisons of enzyme production under the different conditions of oxygen concentration.

These results show a general trend of decrease in production of extracellular enzyme with increased air concentration in the environment. Also associated with increased air in the habitat is a decrease in the maximum specific growth rate. Under conditions of slower growth, biomass production rate is lower and in consequence there is a reduced requirement for rate of supply of nutrients. The bacteria in response to slower growth reduce the production rate of exocellular enzymes which are required for the supply of low molecular weight cell membrane transportable nutrients. These originate in the natural environment from high molecular weight polymers or phosphorylated carbon sources. The requirement for high levels of extracellular enzyme production is not necessary with these bacteria because, firstly, these enzymes are stable in the skin environment and, secondly, the environment is composed of solid surfaces and low water content which reduces enzyme dilution and increases efficiency of the enzyme.

The presence of N-acetylglucosamine in P. acnes cultures requires further investigation. It appears to originate from the P. acnes cells, i.e. cell walls or possibly capsular material and not from the medium, since it is not detected in hyaluronidase-producing cultures of P. granulosum. The liberation of inorganic phosphate by the growth of cutaneous propionibacteria is probably a result of dephosphorylation of nutrients prior to transport into the cells. The role and regulation of acid phosphatase in P. acnes warrants further study.

Further experiments will examine the physiological effects of oxygen on the cutaneous propionibacteria. Oxygen toxicity and the protective measures that bacteria elaborate have been reviewed by Morris (1975). It is well known that cutaneous propionibacteria possess catalase (Marple & McGinley, 1974), but the presence and regulation of other enzymes such as NADH oxidase and superoxide dismutase have yet to be studied in these bacteria. It is also possible that oxygen is important in the regulation of cytochrome synthesis in cutaneous propionibacteria as has been shown in Propionibacterium shermanii (Pritchard et al., 1977). Roberts (1975) reported that P. acnes was capable of oxygen utilization. Studies preliminary to these experiments also showed that cutaneous propionibacteria were capable of reducing the oxygen concentration of their environment. It is not known if this is simply an oxygen detoxifying mechanism or if the cells obtain energetic advantage from the presence of oxygen.

The results of this investigation support the view that changes in extracellular enzyme production altered by propionibacterial growth rate would occur in vivo as a result of a change in the oxygen tension of the pilosebaceous duct or due to exposure of the bacteria at the skin surface. Therefore the oxygen tension in individual follicles may well affect the interaction of the propionibacteria with their environment.
