Flocculation of a *Methylomonas* sp.: Possible Involvement of a Surface Protein

By GURI EGGSET,† EVEN STENBERG‡ and JOH. KJOSBAKKEN*

Department of Biochemistry, The Norwegian Institute of Technology, N-7034 Trondheim – NTH, Norway

(Received 21 June 1983; revised 8 August 1983)

Chemostat-grown cells of a newly isolated strain of *Methylomonas* were flocculated by the addition of small amounts of positively charged flocculants. The flocculation ability of the cells was almost completely lost after extracting the cells with 1–5 mM-EDTA, or by reducing pH below 4.5. Reconstitution of the flocculation ability of EDTA-extracted cells was obtained either by the addition of an excess amount of calcium ions, or by mixing dialysed EDTA extracts with EDTA-extracted cells. The EDTA extract contained mainly proteins. The major protein was purified to homogeneity by gel filtration, and had a molecular size of 65,000 Dal and an isoelectric point of 9.0. Immunological techniques indicated that this protein was located on the surface of the bacteria. We, therefore, propose that the surface protein of the *Methylomonas* sp. is involved in flocculation by positively charged flocculants.

INTRODUCTION

Flocculation as a means of separating bacteria from their growth medium is of considerable industrial importance. The efficiency of the activated sludge process for the treatment of effluent water depends to a large extent on bacteria which flocculate naturally during growth (Harris & Mitchell, 1973; Pipes, 1978). Growth of bacteria for the industrial production of cell material (single cell protein), enzymes or metabolites depends on cheap methods of harvesting cells. This goal can be achieved very efficiently by inducing the cells to flocculate after growth in the fermenter (for reviews see Atkinson & Daoud, 1976; Wang & Sinskey, 1970).

In the past decade there has been considerable interest in utilizing bacteria grown on cheap carbon sources like methanol or methane for the production of protein-rich animal feed-stuff, and several processes have been proposed (Mogren, 1979; Senior & Windass, 1980). A flocculation step for cell harvesting seems to be an integral part in these processes, and a number of such methods have been developed empirically. Little information concerning the detailed mechanisms underlying the various flocculation procedures is available.

In the present paper a *Methylomonas* sp. was flocculated with a positively charged, commercially available flocculant. We have studied this flocculation mechanism in some detail, and present evidence for the possible involvement of proteins located on the bacterial surface in the flocculation process.

METHODS

**Bacterial strain and growth conditions.** A methanol-oxidizing bacterium was isolated as described by Hågström (1975) and identified as a *Methylomonas* sp.

The strain was cultured continuously in a 4 litre fermenter (Chemoferm AB, Stockholm, Sweden) at a dilution rate of 0.1 h⁻¹. The medium with growth-limiting amounts of methanol (114 mM) was as described by Hågström.
Centrifugation (6000 g) at steady state conditions. The vessel stirring rate was 1000 r.p.m. and sterile air was supplied at a rate of 2 L min⁻¹. Cells were harvested by treatment a concentration of 2 mg enzyme ml⁻¹ was used at 40 °C for 1.5 h. Cells were treated at low pH by adding 1 M-HCl and stirring for 1 h at 20 °C. In some experiments the pH was readjusted to 6.6 by the addition of 1 M-NaOH and the suspension was incubated further for 1 h. The cells were always washed and resuspended in phosphate buffer prior to flocculation.

**Flocculation experiments.** The harvested cells were washed twice with 10 mM-sodium phosphate buffer, pH 6-6, and resuspended in the same buffer to 1-6 g cells (dry wt) 1⁻¹. This suspension is referred to as washed cell suspension. The washed cell suspension (10 ml) was mixed with 10-100 µg of the flocculant in water (0-2 mg ml⁻¹), and stirred for 5 min at 100 r.p.m. The aggregates formed were sedimented by centrifugation for 5 min at 120 g, and the turbidity of the supernatant was measured at 660 nm. The percentage flocculation was calculated as follows:

\[
\text{Percentage flocculation} = 100 \left(1 - \frac{\text{OD}_{S}}{\text{OD}_{O}}\right)
\]

where \(\text{OD}_S\) = turbidity of the supernatant after removal of flocculated cells, and \(\text{OD}_O\) = turbidity of the cell suspension before flocculation.

**Treatment of bacterial cells.** Extraction with EDTA was performed by mixing washed cell suspensions with a solution of EDTA in 10 mM-phosphate buffer, pH 6-6, to a final concentration of 1-6 g cells (dry wt) 1⁻¹ and 1-10 mM-EDTA. The mixture was incubated with stirring for 1 h at 20 °C, and the cells were sedimented by centrifugation, washed twice and resuspended in phosphate buffer before flocculation as described above. The EDTA-containing extract was used for further analysis.

For reconstitution of extracted protein on bacterial cell walls, cells extracted with 1 mM-EDTA and washed were mixed with a 1 mM-EDTA extract previously dialysed for 24 h at 4 °C against 1 mM-CaCl₂ in phosphate buffer. The mixture was incubated with gentle stirring for 20 h at 4 °C. Alternatively, reconstitution was performed by the addition of 2-5 mM-CaCl₂ to the cell suspension subsequent to extraction with 1 mM-EDTA and incubation for 1 h.

Urea treatment of washed cell suspensions was carried out by stirring with 1 M-urea at 37 °C for 2 h. For papain treatment a concentration of 2 mg enzyme ml⁻¹ was used at 40 °C for 1.5 h. Cells were treated at low pH by adding 1 M-HCl and stirring for 1 h at 20 °C. In some experiments the pH was readjusted to 6-6 by the addition of 1 M-NaOH and the suspension was incubated further for 1 h. The cells were always washed and resuspended in phosphate buffer prior to flocculation.

**Gel filtration.** Extracts from cells treated with 5 mM-EDTA were concentrated 50-fold by ultrafiltration (Amicon, Diaflo filter PM 10), and fractionated on a column of Sepharose CL6B (16 × 700 mm) with 50 mM-phosphate buffer, pH 6-6. Combithek Calibration Protein II markers (Boehringer, Mannheim) were used as standards to estimate molecular sizes.

**Electrophoresis.** EDTA extracts, or fractions from the gel-filtration column were incubated with 1% (w/v) SDS and 1% (v/v) mercaptoethanol for 2 h. Disc electrophoresis was performed on 10% polyacrylamide gels in 0.1% SDS as described by Weber & Osborn (1969). The gels were stained with Coomassie brilliant blue R250 (Bio-Rad). Low molecular weight protein standards (Bio-Rad) were used to estimate molecular sizes.

**Electrofocusing.** Crude EDTA extracts, or purified protein, were applied as 10 µl drops on an Ampholine polyacrylamide gel plate (gel concentration 2-4%, supplied by LKB, Sweden) with a pH range of 3-5-9-5. Focusing was performed in the LKB Multiphor System at constant power (25 W). The pH gradient was determined with a surface electrode (LKB). The proteins were fixed with 3-5% (w/v) sulphosalicylic acid and 11-5% (w/v) trichloroacetic acid in water before staining with Coomassie brilliant blue R250 (1-15 g l⁻¹ destaining solution), and destaining against several changes of destaining solution (25% (v/v) ethanol and 8% (v/v) acetic acid in water).

**Production of antiserum.** Purified protein [1 mg (ml saline)⁻¹] was intravenously injected weekly in a rabbit for 3 weeks. The rabbit was bled one week after the last injection. The blood was first incubated 4-5 h at room temperature and then overnight at 4 °C before the serum was pipetted off. This antiserum was used in the bacterial agglutination test, which was performed by mixing a suspension of bacteria (20 µl) with an equal volume of diluted antiserum on glass plates. The highest dilution of antiserum which still gave visual agglutination was used as a semiquantitative index of agglutination.

**Other methods.** Protein assays were performed according to Bradford (1976) using the Bio-Rad dye assay reagent based on Coomassie brilliant blue G250. Polysaccharides were determined as glucose equivalents from the reaction with anthrone (Scott & Melvin, 1953). RNA was analysed by the orcinol method (Ashwell, 1957).

Purified protein (5 mg ml⁻¹) was hydrolysed in 6 M-HCl at 110 °C for 24 and 68 h. The hydrolysates were washed twice in distilled water before chromatography on an automatic amino acid analyser (Beckman, model 120C).

**RESULTS**

**Flocculation of bacterial cells**

Chemostat-grown cells were easily flocculated by the addition of several commercially available flocculants (Allied Colloids, Bradford, UK and Crosfield Polyelectrolytes, Warrington,

U.K.). The flocculants were mostly positively charged, soluble polyacrylamide or polyamine based polymers. Details of their chemical structures were not available. One suitable flocculant, Zetag 76 (Allied Colloids), was chosen for further experiments. Complete flocculation was achieved at concentrations of 3 µg (ml Zetag 76)⁻¹ (Fig. 1). The flocculation of cells by Zetag 76 was used as a model system for further studies on the mechanism of flocculation.

Treatment of cells with surface-modifying agents

Regular patterns of protein layers on the surface of various bacteria have been described in several reports (for a review, see Sleytr, 1978). To study their possible involvement in the flocculation of our *Methylomonas* sp. several methods were used to disorganize or extract these layers.

Treatment of washed cell suspensions with urea or papain had only negligible effects on their flocculation. Cells which were incubated at pH 2.0 or 4.5, however, lost most of their flocculation ability (Fig. 1). No release of protein could be observed after this treatment. Flocculation was not restored by prior incubation at pH 6-6.

Treatment of a washed cell suspension with 1, 5 or 10 mM-EDTA drastically reduced the flocculation ability (Fig. 1). At low concentrations of Zetag 76 the effect of the three different EDTA concentrations was similar. Treatment with 1 mM-EDTA gave no apparent lysis of the cells, as judged by turbidity and RNA analysis, and this concentration was used for further flocculation experiments.

An appreciable amount of protein (70 µg ml⁻¹) was released on treatment with 1 mM-EDTA, while the amount of RNA (7 µg ml⁻¹) and carbohydrate (8 µg ml⁻¹) liberated was low. The protein released accounted for 4.4% of the dry weight of the bacterium. SDS-electrophoresis of the EDTA extracts (Fig. 2a) revealed one dominant protein band corresponding to a molecular size of 65000 Dal (denoted as the major protein), two minor bands with molecular sizes 45000 and 34000 Dal, and approximately ten very weak bands. Extraction of the cells with 5 mM-EDTA instead of 1 mM-EDTA released more protein; up to 190 µg ml⁻¹. The increase was mainly due to the liberation of more of the major protein (Fig. 2a).

Isolation and characterization of the major protein

The major protein was purified to homogeneity by gel filtration of a concentrated EDTA extract on Sepharose CL 6B. The major protein appeared as the dominating peak in the elution
Fig. 2. Separation of proteins released by EDTA extraction of chemostat-grown cells of a *Methylomonas* sp. (a) SDS gel electrophoresis of 1 mM and 5 mM-EDTA extracts. Samples were incubated in 1% SDS and 1% mercaptoethanol for 2 h prior to electrophoresis through 10% (w/v) acrylamide gels containing 0.1% SDS. Standard proteins were run on separate gels (not shown). Molecular sizes of sample proteins are indicated. (b) Gel filtration of a 5 mM-EDTA extract on Sepharose CL 6B. The molecular sizes of the major protein and standard proteins are indicated by arrows.

profile (Fig. 2b). A molecular size close to 65000 Dal was estimated by running protein standards on the same column. This was in agreement with the molecular size determined by SDS–electrophoresis.

Isoelectric focusing of the protein in ampholine gel revealed an isoelectric point of 9.0 ± 0.2. This high value was confirmed by preliminary amino acid analysis (Table 1), which indicated an excess of basic amino acids. The major protein thus appeared to be a basic protein.

*Reconstitution of flocculation ability*

The flocculation ability which was lost by EDTA extraction could be restored by adding CaCl₂ in excess. Cells treated with EDTA, but not washed, regained most of their flocculation ability on incubation with CaCl₂ (Fig. 3).

Freshly extracted and washed cells regained 85% of the flocculation ability after incubation with an EDTA extract dialysed against Ca²⁺-containing buffer (Fig. 3). We were not able to restore the flocculation ability of EDTA-extracted cells by the addition of the purified major protein, at concentrations of up to approximately 50 mg (g dry wt cells)⁻¹.

**Bacterial agglutination test**

Antiserum raised against the purified major protein easily agglutinated a suspension of washed bacterial cells up to a serum dilution of 1:128 (when mixed 1:1). This strongly indicated that the major protein was located on the bacterial cell surface. Bacteria extracted with 1 mM-EDTA and washed were agglutinated only up to 1:32 serum dilution indicating that far less protein was available for agglutination. Serum obtained from non-immunized rabbits gave no detectable agglutination.

**DISCUSSION**

To study the mechanism of flocculation, we have consistently used washed bacteria to avoid interference by the growth medium or extracellular polysaccharides produced by *Methylomonas* (Häggström, 1975). Most bacteria have negatively charged surfaces at neutral pH (Harden & Harris, 1953). Our *Methylomonas* sp. was readily flocculated with positively charged polymers indicating the presence of negative charges on the surface of this strain.

The treatment of the strain with 1 mM-EDTA liberated protein and small amounts of carbohydrate and RNA. According to Leive & Morrison (1972), the carbohydrate might be part of the lipopolysaccharide. The amount of RNA released was low, indicating negligible lysis of the cells. Lysis could not be observed microscopically. Only 4% of the EDTA-treated cells,
however, could form colonies on agar medium. It has been postulated that major outer-membrane proteins may be essential for Gram-positive (Howard & Tipper, 1973) and for some Gram-negative bacteria (Osborn & Wu, 1980).

The major protein with a molecular size of about 65000 Dal represented more than 50% of the total proteins extracted with EDTA from chemostat-grown *Methylomonas* sp. It is possible that this protein covers the cell surface, possibly in a regular pattern. Such layers have been described for many different bacteria including a *Methylomonas* sp. (Wilkinson, 1971). Our results have indicated that such a possible protein layer may be attached to the cell surface by means of divalent cations. Ca\(^{2+}\) or Mg\(^{2+}\) was reported to be required for the attachment of the major protein on the surface of an *Acinetobacter* strain (Thorne, 1977). Furthermore, it has been found that *Spirillum serpens* contains surface protein only in the presence of Ca\(^{2+}\) (Buckmire & Murray, 1970).

As the major protein of our *Methylomonas* sp. might cover the cell surface, it could be responsible for cell flocculation on addition of positively charged flocculants. The flocculation ability was lost almost completely when this protein was removed by EDTA extraction. We were able to restore much of the flocculation ability by opposing the effect of EDTA (adding excess Ca\(^{2+}\) or removing EDTA). This may lead to reconstitution of protein on the cell surface. We were not able to restore flocculation ability by mixing the purified major protein with cells extracted with EDTA in the presence of Ca\(^{2+}\). This could be due to removal during the purification process of carbohydrate components (Masuda & Kawata, 1981), LPS (Osborn & Wu, 1980), or other components essential for the reconstitution. However, the flocculation could be more complex than we have suggested, depending on several surface proteins and other components liberated by EDTA.

Low pH has been reported to denature bacterial cell surface proteins (Sleytr & Thorne, 1976). In our case, pH lower than 4.5 irreversibly abolished the flocculation ability of the cells, possibly by denaturing surface protein. Negligible amounts of protein were released on treatment at low pH.

Cells grown in batch culture without pH control could be flocculated when harvested from the exponential phase, but not after entering the stationary phase where pH would have dropped to below 5.0. EDTA extraction of cells from exponential phase gave mainly the major protein, while extraction of stationary-phase cells released only small amounts of this protein and several other proteins dominated (data not shown).

The major protein (65000 Dal) appears to consist of one single polypeptide chain with isoelectric point close to 9 and with more basic than acidic amino acids. At pH 6-6 there would be a total surplus of positive charges on this protein. To bind a positively charged flocculant we must postulate that there are negative regions available on the bacterial surface, and the major protein might have a configuration *in situ* which makes this possible. Major outer-membrane proteins isolated from other bacteria seem to be more acidic than the protein which we have isolated from a *Methylomonas* sp. *Bacillus sphaericus* has a major surface protein with 10–15% excess of acidic amino acids (Howard & Tipper, 1973). Surface proteins from *Vibrio cholerae* and a strain of *Acinetobacter* were also acidic (Kabir, 1980; Thornley et al., 1974).

Endo et al. (1976) and Endo & Takahashi (1980) have shown that the flocculation of a naturally flocculating strain of *Flavobacterium* was lost after EDTA or pronase treatment. Flocculation could be partially restored by the addition of calcium ions, indicating that surface proteins were involved in flocculation.

This work was supported by a grant from the Royal Norwegian Council for Scientific and Industrial Research. We acknowledge the able technical assistance of Mrs Anne-Lise Ustad.
