Production of Methanethiol from Methionine by *Brevibacterium linens* CNRZ 918

By M. FERCHICHI,* D. HEMME, MICHELE NARDI AND NICOLE PAMBOUKDJIAN

Laboratoire de Microbiologie Laitière, Institut National de la Recherche Agronomique, CNRZ, 78350 Jouy-en-Josas, France

(Received 8 August 1984; revised 13 November 1984)

The conditions under which *Brevibacterium linens* CNRZ 918, a strain isolated from the surface smear flora of Gruyère de Comté cheese, produced methanethiol from methionine were studied. Demethiolation was estimated from the methanethiol production capacity of resting cells. Methionine was demethiolated mainly during the exponential growth phase of the organism during which time the cells were rod-shaped and had a generation time of 5 h, and the medium became alkaline. At the end of growth (pH 9) the cells were coccoid, and produced only very little methanethiol. The production of methanethiol required the presence of methionine in the culture medium, this reflecting the probable induction of the enzyme systems involved. Glucose favoured growth and inhibited production of methanethiol. Lactate favoured both growth and methanethiol production.

Resting rod cells also produced methanethiol from structural analogues of methionine and from methionine-containing peptides. The apparent kinetic constants of the production of methanethiol for rod and coccoid cells were respectively $K_m = 14 \text{ mM}$ and $46 \text{ mM}$, $V_{max} = 208 \text{ nkat g}^{-1}$ and $25 \text{ nkat g}^{-1}$. The optimum temperature and pH for production were 30 °C and pH 8. Azide or malonate favoured the production of methanethiol by resting cells, whereas chloramphenicol had no effect.

**INTRODUCTION**

Certain surface-ripened cheeses such as the French varieties Pont l'Evêque, Munster, Livarot, Vacherin and Camembert typically exhibit flavours variously described as 'cabbagey', 'garlic' or even 'putrid' (Adda *et al.*, 1978; Hemme *et al.*, 1982; Boyaval & Desmazeaud, 1983). These flavours are attributable to sulphur compounds of varying complexity (Cuer *et al.*, 1979), which arise from the condensation of precursors either with or without the intervention of the enzyme systems of the microflora (Badings *et al.*, 1975; Boelens *et al.*, 1975; Cuer *et al.*, 1979a, b; Forss, 1979). Methanethiol is found in all these cheeses, and always seems to arise by microbiological degradation of methionine (see Hemme *et al.*, 1982).

Numerous micro-organisms can produce methanethiol from methionine (Kadota & Ishida, 1972), including those commonly predominating in the microflora of cheeses (Richard & Zadi, 1983) such as diverse species of *Penicillium* (Ruiz-Herrera & Starkey, 1969a), yeasts (Schreier *et al.*, 1976), *Pseudomonas* (Ito *et al.*, 1976; Tanaka *et al.*, 1977; Esaki *et al.*, 1977; Laakso, 1979) and coryneform bacteria (Segal & Starkey, 1969; Sharpe *et al.*, 1976; Sharpe *et al.*, 1977; Law & Sharpe, 1978). Micro-organisms isolated from other sources such as soil and the rumen (Mitsuhashi & Matsuo, 1950; Merricks & Salsbury, 1975) as well as *Clostridium sporogenes* (Kreiss & Hession, 1973) and *Escherichia coli* (Ohigashi *et al.*, 1951) are also known to produce methanethiol from methionine.

**Abbreviations:** BM, basal medium; DTNB, 5,5'-dithio-bis-2-nitrobenzoic acid; MTPC, methanethiol production capacity; sMTPC, specific methanethiol production capacity.
The predominant surface rind flora of the orange-coloured smear-ripened cheeses such as Munster, Pont l'Evêque or Livarot is composed of strains related to Brevibacterium linens. This organism also forms a high proportion of the surface rind flora of other cheeses such as Gruyère de Comté and Beaufort (Accolas et al., 1978) or Camembert made from raw milk (Richard & Zadi, 1983). Most of the strains of B. linens isolated from these three cheese types were able to produce methanethiol by demethiolation of methionine (D. Hemme & J. Richard, unpublished results).

The present paper reports the effects of different conditions on the production of methanethiol from methionine by B. linens.

METHODS

Strain. Brevibacterium linens CNRZ 918 was obtained from the culture collection of the Centre National de Recherches Zootechniques (CNRZ). This strain was originally isolated in J. E. Auclair's laboratory by Accolas et al. (1978) from the surface rind flora of Gruyère de Comté cheese.

Media. The basal medium (BM) had the following composition (g l⁻¹): meat extract (Merck) 4.0, yeast extract (Difco) 3.0, bactotryptone (Difco) 10.0, KH₂PO₄ 4.0, NaOH (pellets) 1.0. To this basal medium was added L-methionine (Sigma) 1.0, D-glucose (Sigma) 5.0, or Dl-sodium lactate (Sigma) 5.0. The pH of the media, initially between 7.4 and 7.6, decreased by 0.2 pH unit after autoclaving at 120 °C for 20 min.

Cultures. To ensure good reproducibility throughout the series of experiments, a stock of frozen cultures was constituted by inoculating (5%) a series of tubes of 20 ml BM, and without incubating, freezing them at −20 °C. At the start of each experiment a frozen culture was thawed, transferred to a 100 ml capacity Erlenmeyer flask and incubated at 20 °C for 24 h. This constituted the preculture which was then used to inoculate (1 to 2%) the experimental culture. Experimental cultures were similarly grown in 1000 ml capacity Erlenmeyer flasks filled to 20% capacity and shaken at 250 g for 20 min at 4 °C (Sorvall). The cells were resuspended in 5 ml 50 mM-Tris/HCl buffer (Trizma, Sigma) at pH 8.0 and 4 °C, and then washed twice and resuspended in the same buffer.

To measure MTPC, the reaction mixture (1·5 ml) consisted of 1·25 ml of cell suspension in the buffer (OD₆₅₀ = 0·8, corresponding to 0·48 mg dry wt ml⁻¹) to which was added 84 μl 5 mM-DTNB (5·5'-dithio-bis-2-nitrobenzoic acid; Aldrich) dissolved in pure ethanol (final concn. 960 mm) and 168 μl of 134 mM-substrate. The following substrates (all from Sigma) were used: L-methionine, L-methioninamide HCl, L-alanyl-L-methionine, L-methionyl-L-alanine, L-ethionine, α-keto-γ-methiolbutyric acid, N-formyl-DL-methionine, DL-methionine-S-methylsulphonium chloride, DL-methionine-α-hydroxy analogue, and DL-methionine sulphoxide. Controls comprised the reaction mixture without cells, and the reaction mixture without substrates.

After a reaction time of 1 h at 30 °C, MTPC was estimated from the yellow colour (read at 412 nm against controls without substrates and without cells) produced by the reaction of DTNB with methanethiol liberated from the substrate. This reaction time was chosen as the methanethiol production was directly related to time incubation for up to 2 h. The concentrations of methanethiol were determined from a linear standard graph obtained with solutions of known concentrations of ethanethiol between 6 and 60 μM. The specific methanethiol producing capacity (sMTPC) of the cells was defined as nmol methanethiol produced s⁻¹ (g dry wt of cells)⁻¹ [nkat (g dry wt)⁻¹ or nmol s⁻¹ g⁻¹] from the substrate, under the conditions of assay.

Reproducibility. All results presented in this paper are the mean of three or more replicate assays. Variations observed were always less than 10%.

RESULTS

Variation of the specific methanethiol producing capacity (sMTPC) of cells with growth phase. The growth of B. linens CNRZ 918 exhibited a lag phase of 30 h. This was followed by a slow rate of exponential growth, accompanied by alkalinization of the medium, the pH reaching 9·0 and the OD₆₅₀ 17·0 at the end of growth (Fig. 1). The generation time in the basal medium (BM), either supplemented with 6·7 mM-methionine or not supplemented, was approximately 5 h. Short rod-shaped cells predominated in the culture until 48 h (OD₆₅₀ ≈ 4·0), after which coccoid forms appeared progressively, representing approximately 10% of the cells after 55 h incubation and 100% at the end of growth (Fig. 2).
Production of methanethiol by B. linens

Fig. 1. Growth (○,●), changes in pH of the culture (□,■) and sMTPC of harvested cells (▲,▲) during growth of B. linens at 26 °C in BM (open symbols) and in BM + methionine (filled symbols).

Fig. 2. Different morphological forms of B. linens CNRZ 918 obtained during growth in BM + methionine: (a) rod form at the beginning of division; (b) short rounded form (club form); (c) coccoid form; (d) diplococcoid form. The bar marker represents 500 nm.
Fig. 3. Effect of the addition of glucose to the medium (BM + methionine) during growth at 26 °C of *B. linens* CNRZ 918 on the pH of the culture (●, control without glucose; ■, 0.5% glucose; □, 1% glucose; ○, 2% glucose) and on the sMTPC of the harvested cells (∆, control without glucose; Δ, 1.0 or 2.0% glucose). The arrows indicate the addition of glucose to the culture, 36 h after the start of the experiment.

The sMTPC of the cells increased during culture in BM + methionine to a maximum of 53 nkat g⁻¹ obtained after 55 h incubation (OD₆₅₀ = 11.0; pH 8.0), and thereafter decreased progressively as coccoid forms became predominant. The sMTPC of the cells was more than three times greater in BM + methionine than in non-supplemented BM.

**Influence of carbon source on the sMTPC.** After 48 h growth, the OD₆₅₀ in BM + methionine + lactate (7.2) was 80% greater than that in BM + methionine (4.0). But the sMTPC of the BM + methionine + lactate grown cells [44 nkat (g dry wt)⁻¹] was only 10% greater than that of the BM + methionine grown cells [40 nkat (g dry wt)⁻¹]. In BM + methionine + glucose, the OD₆₅₀ after 48 h (4.8) was 20% greater than that in BM + methionine, but the sMTPC of the cells [20 nkat (g dry wt)⁻¹] was only half that of the BM + methionine grown cells.

However, when glucose was added (1 or 2%) to BM + methionine after an initial 36 h growth period, the sMTPC dropped to 10% of that of cells in the control BM + methionine (Fig. 3). The addition of higher concentrations of glucose did not bring about a greater effect on the sMTPC.

When 0.5% glucose was present in the BM + methionine from the start, no acidification of the medium occurred. However, when glucose was added after 36 h, the medium was initially acidified, the extent of the acidification increasing with increase in the concentration of glucose up to 1% (Fig. 3). The medium subsequently became alkaline at the same rate as the control cultures grown in BM + methionine, except at the level of 2% glucose. This irreversible effect of 2% glucose was accompanied by a substantial change in cell morphology, in particular thickening of the envelope and invaginations of the membrane (Fig. 4) which was not observed at lower concentrations of glucose nor in the presence of lactate.

**Influence of cell concentration on the MTPC.** For the coccoid forms, the MTPC increased with increasing cell concentration between 0.5 and 4.0 mg dry wt of cells ml⁻¹ (Fig. 3). In contrast, the MTPC of the rod forms decreased at cell concentrations above 1.2 mg dry wt ml⁻¹.

**Effect of storage of cells at −20 °C and 1 °C on sMTPC.** Cells stored frozen at −20 °C for 45 d showed no loss of ability to produce methanethiol, irrespective of whether they were rod-shaped or coccoid. In contrast, both cell forms exhibited substantial loss of activity when held at 1 °C for 15 d (40% in the case of the rods, and 28% in the case of the coccoid forms).
Production of methanethiol by B. linens

Fig. 4. Atypical form of B. linens CNRZ 918 obtained in cultures grown in BM + methionine supplemented with 2.0% glucose, showing invaginations of the membrane (G) and thickening of the envelope (r). The bar marker represents 500 nm.

Fig. 5. Effect of cell concentration on the MTPC of rod (△) and coccoid (○) forms of B. linens CNRZ 918 measured with harvested cells.

Fig. 6. Influence of the L-methionine concentration on the sMTPC of (a) rod and (b) coccoid forms of resting cells of B. linens CNRZ 918 represented according to Woolf (1932). r, correlation coefficient.

Apparent affinity of the cells for methionine. The sMTPC of the harvested resting cells increased as the concentration of L-methionine in the assay mixture was increased. This occurred for both the rod and coccoid forms. However, while the saturating concentration of L-methionine was of the order of 100 mM for both forms, the apparent affinity exhibited by the rod forms (apparent $K_m = 14$ mM) was three times as great as that exhibited by the coccoid forms (apparent $K_m = 46$ mM) (Fig. 6a, b).
Rod cells were harvested after 55 h growth in BM + methionine and their sMTPC determined as described in Methods.

Effect of the pH of the suspending buffer on the sMTPC. The maximum production of methanethiol by resting cells suspended in 50 mM-Tris/HCl buffer was obtained at pH 8.0 in the case of both rod and coccoid forms. For the rod forms, the activity at pH 7.5 and at pH 8.5 was approximately 25% of that obtained at the optimum. There is agreement between the fact that the sMTPC of resting cells is maximal at pH 8.0 and the fact that the greatest sMTPC is obtained with cells harvested from cultures at pH 8.0.

Effect of temperature on the sMTPC. The optimum temperature for the production of methanethiol under the assay conditions was 30 °C for the rod forms, and close to 35 °C for the coccoid forms. These temperatures are higher than the optimum growth temperature of the strain (26 °C). When the strain was cultivated at a temperature higher than 30 °C, coccoid forms rapidly predominated in the culture, which consequently became less active with respect to production of methanethiol.

Action of metabolic inhibitors, chloramphenicol and structural analogues of methionine on the sMTPC. Sodium malonate and sodium azide both increased the sMTPC of the rod-shaped cells (Table 1); the lowest concentration of sodium azide used (5 mM) effected the greatest increase of the sMTPC.

Chloramphenicol (150 μM) had no effect on the production of methanethiol when added to the buffered suspension of rod-shaped cells and incubated for up to 3 h at 30 °C.

Increases in sMTPC of resting rod cells were obtained when a number of structural analogues of methionine were used as substrates (Table 2). Taking the sMTPC obtained with L-methionine
as substrate as 100%, sMTPC values of 470%, 250% and 120% were obtained when L-methioninamide, the peptides L-Ala-L-Met or L-Met-L-Ala, and L-ethionine, respectively, were used as substrate. D-Methionine, methionine sulphoxide, and the α-hydroxy analogue of methionine had no or only a weak effect on the sMTPC.

**DISCUSSION**

The sMTPC observed with cells grown in the basal medium is probably the consequence of an induction of one or more enzyme(s) by the L-methionine present in the medium, that effect being reinforced when the medium is supplemented with L-methionine. Indeed, such an induction has been reported for *Achromobacter* (Ruiz-Herrera & Starkey, 1970) and for the fungus *Phomopsis viticola* (Pezet & Pont, 1980), but not for *Pseudomonas fluorescens* (Laakso, 1979), where the enzyme described was constitutive.

The decrease of sMTPC concomitant with the appearance of coccoid forms in the culture may be related to the usual morphological change of coryneform bacteria from rods to cocci, and could be in this case a direct consequence of a fall of the L-methionine (inducer) concentration.

The considerable decrease in the sMTPC of *B. linens* caused by addition of glucose to the BM + methionine medium was not observed with the lower fungi, where both L-methionine and glucose were simultaneously required for methanethiol production (Ruiz-Herrera & Starkey, 1969a, b; Segal & Starkey, 1969). This effect in *B. linens* may be due to a catabolite repression by glucose of one or more enzymes or transport proteins involved in methanethiol production, or to an inducer exclusion. Indeed glucose was a better growth substrate than L-methionine for *B. linens* CNRZ 918. This is perhaps related to the effect of glucose on the thickness of the cell envelopes, as reported by Mulder & Antheunisse (1963).

The apparent kinetic constants determined for whole cells of *B. linens* CNRZ 918 are similar to those found for the demethiolating activity of crude cell-free extract of *B. linens* (D. Hemme, M. Nardi & M. Ferchichi, unpublished data) and for the partially purified demethiolase of *Pseudomonas ovalis* (Esaki et al., 1977). The apparent Kₘ values of the cells of *B. linens* and of the crude cell-free extract are, however, seven times less than that reported for the reference demethiolase (EC 4.4.1.11) of *Clostridium sporogenes* (Kreis & Hession, 1973).

The decrease in the MTPC with increasing cell concentration of the rod form of *B. linens* is a phenomenon almost identical to that reported for *Pseudomonas fluorescens* by Laakso & Nurmiokko (1976). These authors were not, however, able to explain the phenomenon. A reduction in oxygen concentration when high cell densities are used could be important. If so, the rod form is more sensitive than the coccoid form.

The decrease in sMTPC observed when the amino group of methionine is substituted may be tied to the requirement of the demethylase for a pyridoxal phosphate coenzyme which in turn is dependent on the amino group. However, the higher activities obtained with peptides or L-methioninamide probably reflect their easier entry into the cells (with the same or different systems), followed by their hydrolysis (by amidase for L-methioninamide or aminopeptidases for peptides) and consequently a higher intracellular concentration of L-methionine, as described for other species, e.g. *Streptococcus lactis* (Rice et al., 1978).

In contrast to what has been reported for *E. coli* (Ohigashi et al., 1951), *Pseudomonas* sp. (Miwatani et al., 1954), *Aspergillus* sp. (Ruiz-Herrera & Starkey, 1969b) and *Achromobacter starkeyi* (Ruiz-Herrera & Starkey, 1970), azide and malonate did not inhibit the sMTPC of *B. linens* CNRZ 918 but indeed increased it. As these compounds usually decrease the ATP concentration in the cell, it is possible that ATP inhibits the demethylase(s), as has been reported for purified enzyme of *Aspergillus* sp. (Ruiz-Herrera & Starkey, 1969b).

The authors extend their grateful thanks to J.-P. Accolas for providing the strain used in this study, to Micheline Rousseau and Christiane Le Gallo for the electron micrographs, to P. Labbe for his continued interest in the work, and to F. G. Martley for helpful criticism and assistance with the manuscript. One of the authors (M.F.) was supported by a bursary awarded by the Centre International des Etudiants Stagiaires, Paris.
