(Received 24 May 1985; revised 23 September 1985)

The Vibrio alginolyticus prot-T mutant was able to produce haloes of clearing on skim milk/peptone agar plates at 42 °C whereas proteolysis by the wild-type strain was inhibited at 37 °C. The prot-T mutant overproduced the three major alkaline proteases with apparent molecular masses of approximately 28000, 22500 and 19500 (proteases 1a, 2 and 3, respectively). Their synthesis was not markedly repressed by incubation at 37 °C or by non-aeration. Both treatments inhibited protease synthesis in the wild-type strain, which only produced proteases during the stationary growth phase. The prot-T mutant synthesized proteases throughout the exponential and stationary growth phases in peptone medium. High protease activities were induced by glucose or glutamine in stationary phase prot-T cultures that were pre-grown in peptone medium. Glucose or glutamine had the opposite effect on protease activities in stationary phase prot-T, cultures that were pre-grown in minimal medium. Collagenase synthesis was not altered in the prot-T mutant and was repressed by growth at 37 °C or without aeration. The independent control of collagenase synthesis supports the conclusion that there are no regulatory proteins responsible for the overall control of extracellular protease synthesis by temperature, aeration and growth phase in V. alginolyticus.

INTRODUCTION

The Vibrio alginolyticus strain isolated from hides is an aerobic, halotolerant, Gram-negative bacterium, which produces an extracellular collagenase and five extracellular alkaline serine proteases during the stationary growth phase (Welton & Woods, 1973, 1975; Reid et al., 1978, 1980; Long et al., 1981; Hare et al., 1983). Three major alkaline proteases with apparent molecular masses of approximately 28000, 22500 and 19500 (proteases 1a, 2 and 3, respectively) and two minor alkaline proteases with apparent molecular masses of approximately 15500 and 14500 (proteases 4 and 5, respectively) are produced.

Extracellular collagenase and alkaline protease activities in V. alginolyticus are subject to glucose catabolite repression and end-product repression by amino acids and ammonium ions (Reid et al., 1978; Long et al., 1981). The production of collagenase and alkaline protease activity is also influenced by temperature and oxygen, and enzyme synthesis is inhibited when either the growth temperature is raised from 30 to 37 °C or the rate of aeration is reduced (Hare et al., 1981, 1983). The production of alkaline proteases does not involve a specific inducer and they are produced in a minimal medium (Long et al., 1981), whereas collagenase production is only induced by collagen (Reid et al., 1980). The production of alkaline protease activity is markedly enhanced or induced by histidine (Long et al., 1981).

The regulation and production of true extracellular proteases in stationary phase by the Gram-negative V. alginolyticus strain is similar, in a number of aspects, to the secretion of proteases by Gram-positive Bacillus strains (Glenn, 1976; Priest, 1977; Reid et al., 1978, 1980;

Abbreviations: CAM, Casamino acids medium; MM, minimal medium; SMM, succinate minimal medium; NTG, N-methyl-N'-nitro-N-nitrosoguanidine.

Long et al., 1981). Since there are few systems in Gram-negative bacteria for the study of the regulation of exoprotease production, we isolated and investigated the regulation of a V. alginolyticus protease mutant which was insensitive to repression by temperature.

METHODS

Bacterial strain and media. The proteolytic V. alginolyticus strain, which has been described previously (Welton & Woods, 1973, 1975; Reid et al., 1980), was maintained at room temperature on peptone (2.5%, w/v) skim milk. The peptone medium, Casamino acids medium (CAM), minimal medium (MM) and succinate minimal medium (SMM) have been described previously (Long et al., 1980; Hare et al., 1983). All media were prepared in 0.1 M-Tris/HCl buffer (pH 7.6) containing 0.4 M-NaCl and CaCl₂, 2H₂O (0.29 g l⁻¹). Amino acids and carbon sources were added to media to give final concentrations of 0.5 and 0.2% (w/v), respectively.

Growth conditions for enzyme studies. The growth conditions for the production of collagenase in peptone medium and alkaline proteases in SMM, by concentrated stationary phase V. alginolyticus cells, have been described previously (Reid et al., 1980; Long et al., 1981). Cultures were grown overnight in CAM or MM before resuspension in either peptone medium or MM, respectively. After incubation for 3 h the cells were harvested, washed and resuspended in SMM. Cultures were aerated on an orbital shaker at 130 r.p.m. at 30 °C. To facilitate aeration, the cultures were 5–10% of the volume of the flasks, which were covered with loose fitting aluminium foil caps.

Isolation of mutants. Mutagenesis with N-methyl-N'-nitro-N-nitrosoguanidine (NTG) (carcinogen) was done according to Adelberg et al. (1965). NTG (100 µg ml⁻¹) was added to exponential phase V. alginolyticus cells in 0.1 M-Tris/maleic acid buffer (pH 6.0) containing 0.4 M-NaCl and CaCl₂, 2H₂O (0.29 g l⁻¹), and the culture was incubated for 15 min at 30 °C (approximately 10% survival). Washed cell suspensions were resuspended in peptone broth and aerated for 3 h at 30 °C before plating onto skim milk/peptone agar plates. The plates were incubated at 42 °C and observed for colonies which produced zones of clearing surrounding colonies at the elevated temperature.

Enzyme assays. All enzyme assays were done at standardized cell densities. Each sample was assayed in duplicate and experiments were repeated at least three times. Collagenase was assayed by the method of Wunsch & Heidrich (1963) using the synthetic collagenase substrate phenyl-azobenzyloxycarbonyl-L-propyl-L-leucyl-glycyl-L-arginine (Fluka) as described previously (Reid et al., 1978). Alkaline protease activity was assayed using the synthetic substrate azocasein (Sigma) at a concentration of 2% (w/v) in 0.1 M-Tris/HCl buffer (pH 9.0). The sample (1 ml) was added to 1 ml of the azocasein solution and the mixture was incubated at 37 °C for 30 min. The reaction was stopped by the addition of 10% (w/v) trichloroacetic acid (2 ml). After standing at 4 °C for 30 min the mixture was filtered and 1 ml 0.5 M-NaOH was added to 1 ml of the filtrate. One unit of alkaline protease activity is defined as the amount of enzyme that gives an increase in A₄₅₀ of 0.1 in 30 min at 37 °C.

Gelatin-PAGE protease assay. Extracellular proteases produced by V. alginolyticus were characterized by PAGE in slab gels containing SDS and gelatin as a copolymerized substrate (Heussen & Dowdle, 1980) as described previously (Hare et al., 1983). After PAGE the gels were washed in Triton X-100 (2.5%, v/v) for 1 h at room temperature to remove the SDS and restore enzyme activity. After incubation in 0.1 M-glycine buffer (pH 9.0) for 3 h at 37 °C bands of proteolytic activity were detected after staining with 0.2% (w/v) amido black.

RESULTS

Isolation of prot-T₁ mutant

Wild-type V. alginolyticus colonies produced haloes of clearing on skim milk/peptone agar plates at 30 °C but proteolysis was completely inhibited at 42 °C. The bacteria grew and formed normal sized colonies at 42 °C. After mutagenesis with NTG a single colony was isolated which formed an extensive halo at 30 and 42 °C on the skim milk/peptone plates at a frequency of 10⁻³. The mutant which had overcome protease repression by temperature was designated prot-T₁.

Azocasein protease activity

The production of azocasein alkaline protease activity was determined in liquid media. The growth rates of the wild-type and the prot-T₁ mutant were similar in peptone and glucose/peptone media at 30 °C (Fig. 1). However, a marked difference was observed in the production of alkaline protease activity. The wild-type strain produced a very low alkaline protease activity in the peptone medium (Fig. 1). The prot-T₁ mutant produced high protease activity and after 7 h growth in peptone medium approximately 18-fold higher azocasein...
Overproduction of proteases by V. alginolyticus

protease activity than the wild-type strain was obtained. The addition of 0.4% glucose after 2 h growth in peptone broth did not affect the production of protease activity by the wild-type and prot-T1 mutant (Fig. 1).

Growth of the bacteria in CAM and peptone media or MM before washing, concentration and resuspension in SMM markedly affected the response of the cells to the addition of glucose or glutamine. After pre-growth in MM the prot-T1 mutant produced higher protease activity than the wild-type and under these conditions protease activity in the prot-T1 mutant was repressed by glucose and glutamine added at 55 min (Fig. 2). Since the protease activities produced by the wild-type strain under these conditions were so low, it was not possible to determine whether protease production was subject to repression by glucose and glutamine. The addition of glucose or glutamine to concentrated stationary phase cells in SMM, after pre-growth in peptone medium, resulted in very high protease activities in the prot-T1 cultures (Fig. 3). The addition of glucose or glutamine to wild-type cultures also increased protease production but the final protease activities were approximately fourfold lower than in prot-T1 cultures. Glucose or glutamine did not stimulate the growth of the concentrated stationary phase cultures (Fig. 3). Long et al. (1981) reported the stimulation of protease activity by histidine in V. alginolyticus wild-type cells. Similar results were observed in this study with both the wild-type and prot-T1 strains after pre-growth in peptone medium but the protease activities in the prot-T1 mutant obtained with histidine were markedly less than those obtained with glucose or glutamine (Fig. 3).

The production of azocasein protease activity by the wild-type in SMM after pre-growth in MM was reduced by approximately 60% by incubation at 37 °C or approximately 80% by incubation without aeration by shaking (Table 1). The high protease activities of the prot-T1 strain were slightly reduced by these treatments.

**Gelatin-PAGE protease assay**

Determination of alkaline protease activity by the azocasein assay gave an indication of total protease activity but, as the V. alginolyticus strain can produce five different alkaline serine proteases (Hare et al., 1983), it was important to distinguish which proteases were affected in the prot-T1 mutant. The activities of specific alkaline proteases in SMM after pre-growth in MM were determined by gelatin-PAGE.

At 30 °C the wild-type strain produced the same three major protease bands as reported by Hare et al. (1983) (bands 1a, 2 and 3) (Fig. 4). Hare et al. (1983) reported that the activities of the

two minor proteases (bands 4 and 5) varied and that they were always present in small amounts and were often not detected after gelatin-PAGE. In this study the minor protease 4 was detected in the wild-type culture at 30 °C. In comparison with the study by Hare et al. (1983), a new minor protease band (1b) was detected (Fig. 4). At 30 °C the protease band profile of the prot-T$_1$ mutant was similar to that of the wild-type except that the activities of the major proteases (1a, 2 and 3) and the minor protease 5 were enhanced.
Although incubation of the wild-type strain at 37 °C or without aeration markedly inhibited azocasein protease activity, protease activity was detected by the gelatin-PAGE technique (Fig. 4). Lack of aeration or incubation at 37 °C caused a marked reduction in the activity of protease 1a and a reduction in the activities of proteases 1b, 2 and 3. In contrast, the activities of proteases of the prot-T1 mutant were not affected by the lack of aeration. At 37 °C there was a reduction in the activities of the major protease 2 and the variable minor proteases 4 and 5.

The effect of the addition of glucose and (NH₄)₂SO₄ on the activities of proteases was assayed by gelatin-PAGE. The addition of glucose and (NH₄)₂SO₄ to the wild-type cultures at 30 °C resulted in a decrease in the levels of all the proteases (Fig. 4). Activities of the three major proteases 1a, 2 and 3 were still detected but the minor bands 1b, 4 and 5 were either very weak or absent. With the prot-T1 mutant, the activities of the major proteases 1a and 2 were not affected by the addition of glucose but there was a slight reduction in the activity of protease 3. The addition of (NH₄)₂SO₄ to the prot-T1 mutant did not affect the activity of protease 1a but decreased the levels of proteases 2, 3, 4 and 5.

Collagenase production

The production of collagenase by wild-type and prot-T1 cells was determined in peptone medium at 30 or 37 °C, with or without aeration or glucose. The characteristics of collagenase production were identical in the wild-type and prot-T1 strains and similar to those described previously by Welton & Woods (1973, 1975) and Reid et al. (1978, 1980).

DISCUSSION

The regulation of extracellular protease production in the wild-type and prot-T1 mutant of V. alginolyticus differed in a number of respects. The prot-T1 mutant overproduced the three major proteases and their synthesis was not subject to marked repression by temperature or lack of aeration. The temporal expression of protease production was also altered in the prot-T1 mutant and in contrast to the wild-type it produced proteases throughout the exponential and stationary growth phases. The high levels of protease production by the prot-T1 mutant will assist in attempts to clone, express and study the production and secretion of proteases in Escherichia coli.

An interesting difference between the two strains was the very high protease activities obtained with stationary phase prot-T1 cultures supplemented with glucose or glutamine. The pre-growth conditions affected the glucose or glutamine response and an increase in protease activity was only observed when the stationary phase cultures were pre-grown in a rich peptone medium. The addition of glucose or glutamine to stationary phase cultures pre-grown in MM resulted in a decrease in protease activity and a normal glucose (catabolite) or end-product
repression, respectively, of protease activity as reported by Long et al. (1981). The reason for the opposite effects of glucose or glutamine depending on the pre-growth medium is not known. Long et al. (1981) reported that histidine stimulated protease production in the wild-type strain. The stimulation of protease activity by histidine was not altered in the mutant and the protease activities obtained with histidine were much lower than with glutamine.

Collagenase synthesis was not altered in the prot-T, mutant and was repressed by incubation at 37 °C or without aeration. The independent control of collagenase synthesis supports the suggestion that there are no regulatory proteins responsible for the overall control of extracellular protease synthesis by temperature, aeration and growth phase in V. alginolyticus.
