(Received 13 August 1986; revised 1 December 1986)

Strains of Klebsiella pneumoniae of serotype K21 are frequently involved in outbreaks of nosocomial infections. The type strain of Klebsiella pneumoniae K21 (which we have renamed K21a) produces capsular polysaccharide that contains mannose, galactose and glucuronic acid in the ratio 2:2:1. In contrast, all eight of the randomly chosen isolates of Klebsiella pneumoniae that were initially typed as K21 were shown by paper chromatography and NMR spectroscopy to produce a different capsular polysaccharide. We have designated this new polysaccharide K21b. The K21b capsular material appears to have a closely similar immunodominant side chain to K21a. However, K21b polysaccharide has two molecules of rhamnose in the polysaccharide backbone replacing the two molecules of mannose found in the K21a capsule. Our results suggest that the K21b Klebsiella serotype may be more frequently distributed than the classical K21a type.

INTRODUCTION

Klebsiellae are Gram-negative bacilli that characteristically possess a thick polysaccharide capsule. The capsule is antigenic and can induce the production of specific antcapsular antibodies in mammals. At least 83 different capsular serotypes have been recognized (Nimmich, 1968). The capsules of klebsiellae are composed of heteropolymeric polysaccharide with a regular repeating oligosaccharide which often includes mono- or disaccharides as side chains. Sugar derivatives, characteristically glucuronic acid and pyruvylated or acetylated sugars are common constituents of the side chains. The chemical structure of the repeated oligosaccharide unit has been determined for many of the serotypes (Sutherland, 1977). Little diversity exists between the component monosaccharide units of the polysaccharides, variation being achieved by the differential arrangement of the sugar units within the oligosaccharide. However, the limited number of monosaccharides results in many capsules possessing regions of similarity with those from other serotypes. The presence of ketylated, acetylated or acid radicals in particular sugars is an important determinant of the antigenic specificity of a particular polysaccharide. The sugar unit contributing most to the specificity is termed the immunodominant sugar (Luderitz et al., 1966) and this sugar may be terminal or lie within the polysaccharide chain. In branched polysaccharides the immunodominant sugars usually reside within the side chains, which are thus antigenically more important than the backbone. Cross-reactivity between the different capsular antigens of klebsiellae can be correlated with the possession of similar side chains within the oligosaccharide unit.
Klebsiellae are important nosocomial pathogens, primarily causing urinary tract and wound infections (Meers et al., 1981). The pathogenicity of klebsiellae appears to vary between different strains, and serotypes K2 and K21 are much more frequently involved in outbreaks of nosocomial infections than other serotypes (Casewell & Talsania, 1979). The structure of the capsular polysaccharide of Klebsiella type K21 has been elucidated (Choy & Dutton, 1973) and contains mannose, galactose and glucuronic acid in the ratio 2:2:1. However, we have found a number of klebsiellae of serotype K21 that appear to possess a different capsular polysaccharide structure.

**METHODS**

_Bacteria._ The Klebsiella pneumoniae (K. aerogenes) K21 strain U53/1 (redesignated 1L918) was obtained from J. G. Barr, Royal Victoria Hospital, Belfast, Northern Ireland (Barr, 1981). The reference _K. pneumoniae_ K21 (designated 2L222) and seven other randomly chosen Klebsiella K21 isolates (designated 2L225–2L231 respectively) were obtained from the Coventry Public Health Laboratory and the Central Public Health Laboratory (Colindale). The isolates originated in Britain, West Germany and Switzerland.

_Exc**

_Extraction of polysaccharide._ Bacteria were grown on minimal medium, comprising 0.4 g NH₄Cl, 7.5 g Na₂HPO₄, 3.0 g KH₂PO₄, 0.5 g NaCl, 0.2 g MgSO₄, 0.01 g CaCl₂ and 10 g agar in 1 litre distilled water. The cells were then harvested and suspended in distilled water. Extraction of polysaccharide was by the method of Wilkinson et al. (1955). The bacterial capsules were removed by boiling for 10 min and the suspension was centrifuged at 20000 g for 30 min. The supernatant was retained and the capsular polysaccharide was precipitated with 2 vols acetone. The polysaccharide was resuspended in a solution of hydrogen peroxide (4% w/v) and was then deproteinized by shaking 100 ml volumes with 20 ml chloroform and 4 ml butanol-1-ol. The polysaccharide was then reprecipitated with 2 vols acetone, dialysed extensively against tap water, precipitated and freeze dried. Polysaccharide was also extracted by the method of Gotschlich et al. (1969). All steps were performed at 0–4°C. The bulk of the nucleic acids and soluble protein were precipitated by adding 1/3 vol. absolute ethanol. The precipitate was sedimented by centrifugation at 20000 g for 20 min and the supernatant was retained. Three volumes of ethanol were added and the precipitated polysaccharide was collected at centrifugation at 3000 g for 10 min. The polysaccharide was deproteinized by shaking with chloroform and butanol-1-ol as before, and dialysed against 0.1 M-CaCl₂ for 24 h. The polysaccharide solution was centrifuged at 100000 g and 3 vols ethanol were added. The precipitated polysaccharide was collected by centrifugation and dried in vacuo.

_Hydrolysis._ (a) The polysaccharide was hydrolysed in 2 M-HCl for 3 h at 100°C. The hydrolysate was then rotary evaporated and resuspended in 20 μl distilled water. Monosaccharide internal controls were similarly hydrolysed and included in chromatography experiments to determine if destruction of monosaccharides had occurred.

(b) Polysaccharide was partially hydrolysed at pH 2.3 for 3 d at 95°C in an attempt to remove the side chain of the oligosaccharide repeating unit. The hydrolysate was rotary evaporated and dried in vacuo.

_Chromatography._ Hydrolysates were applied to Whatman 3MM chromatography paper and run in butanol-acetic acid/water (4:1:5, by vol.) solvent. The papers were developed with alkaline silver nitrate to allow detection of sugars (Anonymous, 1974).

_Gel diffusion technique for immunoprecipitation._ Agarose (1-1.5% w/v, in 0.05 M-barbitone buffer pH 8.6) was pipetted to form a thin layer on a glass slide. Wells were punched into the gel using a 2 mm diameter cork borer. A 15 μl volume of K21 antiserum (obtained from Coventry Public Health Laboratory) was pipetted into the central well and 15 μl capsular polysaccharide solution (0.1% w/v, in distilled water) was pipetted into the surrounding wells. The gel was incubated in a humid chamber for 48 h at room temperature and then any unprecipitated proteins were eluted by soaking the gel in normal saline for a further 48 h. The gel was dried and stained with Coomassie brilliant blue for 1 h and then destained for 10 min. The gel was then examined for the absence of precipitin lines.

_NMR spectroscopy._ For NMR measurement the different samples of polysaccharide were each dissolved in D₂O, with heating when necessary. K21b polysaccharide that had been partially hydrolysed dissolved without warming.

¹H NMR spectra were measured at 360 MHz on a Bruker AM360 NMR spectrometer at both 30°C and 80°C. Free induction decays (FIDs) were acquired into 32K data points using 60° pulses and a repetition rate of 3:3 s. The accumulated FID was multiplied by an exponential function equivalent to a line broadening of 0.2 Hz before Fourier transformation. Lorentzian–Gaussian transformation of the FID was used to resolve spin couplings in some instances. Chemical shifts in the transformed spectra were referenced to acetate impurity at δ1.95 and in spectra of the partially hydrolysed K21b polysaccharide to internal acetone at δ2.225.

The ¹³C NMR proton decoupled spectrum of the partially hydrolysed K21b polysaccharide was measured at 90 MHz at approximately 30°C. Chemical shifts were externally referenced to dioxan in D₂O at 67.4 p.p.m.

RESULTS

Chromatography of K21 capsular polysaccharide

Purified, hydrolysed capsular polysaccharide extracted from a number of Klebsiella strains of serotype K21 was analysed using paper chromatography. The polysaccharide extracted from the Klebsiella K21 reference strain 2L222 appeared to contain galactose, mannose and glucuronic acid in accordance with the reported structure for K21 antigen (Choy & Dutton, 1973). However, polysaccharide extracted from eight other klebsiellae, including that from strain 1L918, appeared to contain galactose, glucuronic acid and rhamnose rather than mannose. We propose subsequently to refer to the material from the K21 reference Klebsiella as K21a capsular polysaccharide, and to the novel polysaccharide that is present in K. pneumoniae 1L918 as K21b capsular polysaccharide.

Immunoprecipitation of K21 capsular material

Purified polysaccharide extracted from five Klebsiella K21 isolates was analysed using the gel diffusion technique for immunoprecipitation. Each polysaccharide was precipitated by the K21 antiserum and the gels were examined for the formation of spurs which indicate the presence of partial homology between polysaccharides. Spurs were identified between the reference Klebsiella K21a strain and all the other Klebsiella K21 isolates (Fig. 1).

NMR spectroscopy of K21 capsular material

The $^1H$ NMR spectrum of K21a polysaccharide at 80 °C showed signals from five anomic protons, integrating with respect to a three-proton methyl signal at $\sim$δ1.5 typical of CH₃ (pyruvate). This confirmed the presence of five sugars relative to one pyruvate in the repeating unit, as observed previously (Choy & Dutton, 1973). The anomic proton chemical shifts (Table 1) were consistent with four α-linked sugars and one β-linked, the spin coupling on the signal at δ4.9 being typical of β configuration in galactose and glucose sugars.

The $^1$H NMR spectra of K21b polysaccharide isolated both by the method of Wilkinson et al. (1955) and by the method of Gotschlich et al. (1969) were distinctly different from that of K21a polysaccharide. A signal at δ1·35 was characteristic of CH₃ (rhamnose) and by integration corresponded to six protons compared with CH₃ (pyruvate) at δ1·5. This suggests that there are two residues of rhamnose to one of pyruvate in the repeating structure. Rhamnose rather than fucose was the more likely assignment on the basis of the methyl chemical shift, CH₃ (rhamnose) typically being observed at δ1·27-1·36 (Dutton & Lim, 1985; Pritchard & Furner, 1985) and CH₃ (fucose) at δ1·21 (Vliegenhart et al., 1983).

The anomeric proton signals were a broad complex pattern; this probably arose from thermal instability of the polysaccharide, since changes observed in some signals during spectral measurement at 80 °C were irreversible with decrease in temperature. For an estimate of the number of sugars present, all the proton signals in the region δ4·6-5·6 were integrated with respect to the three methyl signals. This indicated 6 ± 1 sugars in the K21b polysaccharide.

The K21b polysaccharide extracted from K. pneumoniae 1L918 was partially hydrolysed to aid the structural determination of the repeating unit. Loss of pyruvate on hydrolysis was confirmed by the almost complete absence of a methyl signal at δ1·5 in the $^1$H NMR (14 equivalent % remained). Two rhamnose units were still present, their methyl signals at δ1·35 each showing a spin coupling of 6·5 Hz typical of $^3$$J_{CH₃-CH₃}$ in rhamnose. Unlike the native polysaccharide, a simple pattern of signals was observed in the anomeric region. Relative integrals of these signals with respect to the methyl signals of rhamnose showed that five anomeric protons were present and therefore that five sugars were in the repeating structure. Chemical shifts and spin coupling constants of the anomeric proton signals may be used to distinguish the sugars present and their anomeric configuration (Bock & Thøgersen, 1982; Vliegenhart et al., 1983). Generally, anomeric proton chemical shifts at 5 p.p.m. and lower field indicate an α configuration and chemical shifts between 4·5 and 5·0 p.p.m. indicate a β configuration. Thus, three sugars in the hydrolysed K21b polysaccharide were assigned α configurations and two β configurations (Table 2). A spin coupling constant ($^3$$J_{H1-H2}$) of 1·5 Hz is typical of rhamnose (De Bruyn et al., 1976). Therefore, from the chemical shifts of the two signals exhibiting this spin coupling, both
Two types of K21 capsule in Klebsiella

Fig. 2. (a) Oligosaccharide structure of K21a polysaccharide (Choy & Dutton, 1973). (b) Proposed structure of the oligosaccharide repeating unit of K21b polysaccharide.

rhamnose sugars possessed \( \alpha \) configuration. A spin coupling constant \( 3J_{\text{H1-H2}} \) of 3.5 Hz is typical of \( \alpha \) configuration in glucose and galactose and that of 8 Hz is typical of \( \beta \) configuration in glucose and galactose. Thus the remaining three sugars present in the hydrolysed K21b polysaccharide were either glucose or galactose, one sugar being in \( \alpha \) configuration and two in \( \beta \) configuration. Distinction of glucose and galactose sugars in the \( ^1\text{H} \) NMR spectrum may be made from the magnitude of the spin coupling constant \( 3J_{\text{H3-H4}} \), but it was not possible to analyse fully the complex spectrum to measure this. Without full spectral analysis it was also not possible to determine whether glucuronic acid rather than glucose was present from the \( ^1\text{H} \) NMR alone. However, the \( ^1\text{H} \) NMR data supported the results obtained by paper chromatography.

\( ^{13}\text{C} \) NMR of the partially hydrolysed polysaccharide (Table 3) further confirmed the assignments of the \( ^1\text{H} \) NMR spectrum. In addition, the presence of glucuronic acid was indicated by a weak signal at 175 p.p.m. assigned to C6 (GlcA). Also the chemical shifts of two signals at 62 p.p.m., typical of C6 in hexopyranose sugars, showed that there was no substitution at −OH on these carbons. From paper chromatography these two sugars were galactose and from \( ^{13}\text{C} \) NMR neither sugar was linked at C6 in the repeating unit.

DISCUSSION

The compositions of the K21a and K21b polysaccharides differ and that of K21b is consistent with the presence of two molecules of rhamnose rather than mannose in the repeating oligosaccharide unit. The high degree of cross-reactivity between the K21a and the K21b polysaccharides would suggest a similar oligosaccharide structure especially with regard to the nature of the side chain. The structure of the K21a repeated oligosaccharide (Choy & Dutton, 1973) is shown in Fig. 2(a). The chromatography results for the K21b polysaccharide material suggest the presence of glucuronic acid, galactose and rhamnose instead of mannose in the oligosaccharide structure. Thus, the structure for the repeated oligosaccharide unit of the K21b polysaccharide may be that shown in Fig. 2(b). The \( ^1\text{H} \) NMR data were consistent with the hydrolysed K21b polysaccharide containing rhamnose, glucuronic acid and galactose in the proportions predicted in the model structure for K21b, with the loss of the pyruvate moiety as a result of hydrolysis. However, because of the uncertainty in determining the number of sugars in the native K21b polysaccharide, any loss of sugar on hydrolysis is not known. In addition, the NMR data were consistent with the hydrolysed K21b polysaccharide containing two \( \beta \)-linked galactose residues whereas K21a polysaccharide contains only one \( \beta \)-linked sugar. Thus, if no sugars are lost on hydrolysis, K21b polysaccharide may possess a side chain with galactose linked to glucuronic acid by a \( \beta \) rather than an \( \alpha \) glycosidic bond as found in the K21a polysaccharide.
Seven randomly selected klebsiellae provided by reference laboratories possessed the K21b-type capsular material produced by *K. pneumoniae* 1L918. Only the reference *Klebsiella* possessed K21a-type material. Given the apparent frequency with which the K21b-type capsule arises as compared to the K21a-type capsule, it is our intention to determine whether this structural variation confers a difference in virulence, for example in resistance to phagocytosis or serum bactericidal activity. This finding also has implications for the epidemiology of infections due to *Klebsiella* of serotype K21 in that it is apparent that this serotype does not form a homogeneous population.
