Molecular Cloning of the Shv-1 β-Lactamase Gene and Construction of an
Shv-1 Hybridization Probe

By UMI BISESSAR† AND RICHARD JAMES*

(Received 17 August 1987; revised 13 October 1987)

We have cloned the Shv-1 β-lactamase gene from the R1010 plasmid into pACYC184. By subcloning and transposon mutagenesis we have localized the gene to a 1-6 kb BscI–SalI fragment of R1010, which is present in the recombinant plasmid pUB8. A 900 bp PstI fragment of pUB8 was shown to be a specific hybridization probe by testing against plasmids which encode 17 different β-lactamase enzymes. A comparison was made of the sensitivity of the Shv-1 probe labelled with either [35S]dCTP or with photobiotin.

INTRODUCTION

The increasing incidence of resistance of Gram-negative bacteria, especially those involved in hospital-acquired infection, to β-lactam antibiotics is principally due to the production of β-lactamase enzymes which inactivate the antibiotics (Medeiros, 1984). Hospital-acquired infection is a leading cause of death in hospitalized patients. Measures to reduce the spread of hospital-acquired infection are critically dependent upon rapid, reliable and relatively cheap methods for the detailed epidemiological investigation of clinical isolates. A variety of methods have been used to classify β-lactamases in clinical isolates, including substrate profiles, inhibition studies, isoelectric points and molecular mass determinations (Matthew, 1979). An alternative method of identification has been described based upon Relative Substrate Affinity Index values (James, 1983), which has been modified by other workers (Eliasson & Kamme, 1985), but the most commonly used method is that of isoelectric focussing of cell extracts in parallel with β-lactamase reference enzymes (Matthew & Harris, 1976; Medeiros, 1984; Simpson et al., 1986). The increasing number of β-lactamase enzymes which have now been characterized, some of which have very similar isoelectric points (Medeiros, 1984), require a combination of tests for satisfactory identification. This is inappropriate for widespread clinical use. Limited surveys of the incidence of β-lactamase enzymes in clinical isolates, many of which were done before the recent large increase in the number of characterized enzymes, have shown that the most common are Tem-1, Tem-2, Shv-1 and Oxa-1 (Matthew, 1979; Simpson et al., 1980, 1986; Stobberingh et al., 1982; Roy et al., 1983; Medeiros, 1984; Levy et al., 1985).

In order to monitor the emergence of 'new' β-lactamases, and to facilitate the epidemiological investigation of hospital-acquired infection involving β-lactam-resistant isolates, gene probes against β-lactamase enzymes appear to offer the most promise. DNA probes against the Tem-1 (Cooksey et al., 1985; Levesque et al., 1987; Ouellette et al., 1987), the Oxa-1 (Ouellette & Roy, 1986; Levesque et al., 1987) and the Rob-1 and Pse-1 β-lactamase genes (Levesque et al., 1987) have been prepared. Here we describe the molecular cloning of the Shv-1 gene and the development of a non-radioactive Shv-1 gene probe.

METHODS

Bacterial strains and media. Escherichia coli JM83 hsdR, a restriction deficient derivative of E. coli JM83 (Ara^- Lac^- Pro^- Thi^- rpsL^80 dlacZM15), was the host for all transformations. It was grown at 37 °C with shaking in LB medium (Miller, 1972), supplemented where appropriate with ampicillin (100 µg ml^-1), or chloramphenicol (15 µg ml^-1).

Plasmids. The R1010 plasmid which encodes the Shv-1 β-lactamase was described by Nugent & Hedges (1979). The cloning vector pUC18 (Vieira & Messing, 1982) was purchased from Pharmacia. The cloning vector pACYC184, which encodes chloramphenicol and tetracycline resistance was described by Chang & Cohen (1978). The E. coli C600 derivatives which contain plasmids determining 17 different β-lactamase types (Jacoby & Sutton, 1985) were kindly supplied by G. A. Jacoby (Massachusetts' General Hospital, USA), and were the source of reference β-lactamase enzymes. Plasmids were prepared by a modification of the method of Birnboim & Doly (1979).

Enzymes and reagents. Restriction enzymes and T4 DNA ligase were purchased from Anglian Biotechnology, Gibco-BRL, Pharmacia or Boehringer. Nitrocefin, a chromogenic substrate of β-lactamase enzymes (O'Callaghan et al., 1972), was purchased from Oxoid and was used following the supplier's recommendations.

Plasmid restriction, ligation, transformations and electrophoresis. Digestion of DNA with restriction endonucleases, ligation of DNA fragments, and transformation of competent cells were done as described by Maniatis et al. (1982). Electrophoresis of DNA fragments was done as previously described (Chak & James, 1984), and specific fragments were recovered from low melting point agarose gels for the labelling of DNA probes.

Transposon mutagenesis. Transposon mutagenesis of plasmid pUB8 with Tn1000 was done as previously described (Chak & James, 1984), after transferring the target recombinant plasmid into E. coli RB308. After conjugation with E. coli RB85, transconjugant colonies were selected on LB agar plates containing streptomycin (200 µg ml^-1) and chloramphenicol (15 µg ml^-1). The resulting colonies were then screened for sensitivity to ampicillin (50 µg ml^-1). Transposon insert sites were located by isolating plasmid DNA from AMP^R colonies and restricting separately with EcoRI, BamHI or HindIII (Guyer, 1978).

Isoelectric focussing. Isoelectric focussing was done by a modification of the method of Matthew et al. (1975), using Ampholine PAG plates with a pH range of 3.5 to 9.5 purchased from LKB. Isoelectric point markers (BDH) and β-lactamase standard enzymes were run in parallel tracks of all gels to allow the accurate identification of the Shv-1 β-lactamase. Cell extracts for isoelectric focussing were prepared by sonication.

Labelling of the Shv-1 gene probe. Specific fragments to be used as gene probes were labelled using [35S]dCTP by using a Multiprime kit (Amersham), or by using photobiotin acetate (Vector Laboratories). With either label the manufacturers' protocols were followed.

Hybridization. Plasmids for hybridization against the Shv-1 gene probes were Southern-blotted onto nitrocellulose filters and then pre-hybridized and hybridized, in the absence of formamide, following the procedure of Mason & Williams (1985). After hybridization overnight at 65 °C, the filters were washed in 2 x SSC/0.1% SDS, 0.2 x SSC/0.1% SDS, and finally in 0.15 x SSC/0.1% SDS at 65 °C before drying. (1 x SSC is 0.15 M-NaCl, 0.015 M-trisodium citrate/citric acid, pH 7.0.)

RESULTS AND DISCUSSION

Cloning of the Shv-1 gene

The R1010 plasmid which encodes the Shv-1 β-lactamase is 89 kb in size (Nugent & Hedges, 1979). After restriction of R1010 with BamHI and ligation with pACYC184 restricted with BamHI, the ligated DNA was transformed into competent cells of E. coli JM83 hsdR, with selection for CMP^R AMP^R transformants. Plasmid pUB3 was isolated from a transformant colony and was shown by restriction mapping to consist of a 6-6 kb BamHI fragment of RlOlO pACYC184 vector. A restriction map was constructed of recombinant plasmid pUB3 (Fig. 1). This plasmid conferred resistance to 500 µg ampicillin ml^-1 on E. coli JM83 hsdR. Using isoelectric focussing, cell extracts prepared from E. coli JM83 hsdR carrying pUB3 were shown to contain the Shv-1 β-lactamase, unlike extracts prepared from this strain carrying pACYC184 alone. In an attempt to localize the position of the Shv-1 gene we constructed subclones of pUB3 (Fig. 1). Deletion of a 1.5 kb BscI fragment of pUB3, from a BscI site in the vector, to the single BscI site in the insert fragment, gave rise to a recombinant plasmid, pUB6, which still encoded ampicillin resistance. The presence of the Shv-1 β-lactamase in cell extracts of E. coli JM83 carrying pUB6 was confirmed by isoelectric focussing. Removal of a 4.1 kb SalI fragment of pUB6, from a SalI site in the vector to the single SalI site in the insert fragment, gave rise to the recombinant plasmid pUB8, which also still encoded the Shv-1 β-lactamase.

![Transposon Insertion Sites](image)

Fig. 2. Tn1000 transposon insertion sites in the 1.6 kb BscI-SalI fragment of PUB8 which inactivate the Shv-1 β-lactamase gene.

Subcloning of the 900 bp PstI fragment of PUB8 into the vector pUC18 restricted with PstI resulted in the recombinant plasmid PUB17. Although this recombinant plasmid conferred ampicillin resistance, due to the Tem-1 β-lactamase gene present in the vector pUC18 (Vieira & Messing, 1982), the absence of the Shv-1 β-lactamase was confirmed by isoelectric focusing of cell extracts. Reversing the orientation of the 900 bp PstI fragment, with respect to the pUC18 lac promoter, did not result in the synthesis of the Shv-1 β-lactamase. No useful restriction sites were found in the 900 bp PstI fragment; this prevented further deletion cloning of this fragment.

**Transposon mutagenesis of PUB8**

In order to obtain more precise information on the localization of the Shv-1 gene we performed Tn1000 transposon mutagenesis of plasmid PUB8. From 450 colonies we identified 32 CMPR AMPS transconjugants and subsequently mapped seven different Tn1000 insertion sites which inactivated the Shv-1 gene (Fig. 2). From the insert sites of number 4 and number 11, the minimum size of the Shv-1 gene and its regulatory elements is 850 bp. This size of DNA fragment has a coding capacity for a 30000 Da protein, which is in good agreement with the reported molecular mass of the purified Shv-1 β-lactamase of 27500 Da (Barthelemy et al., 1986), but not with the value of 17000 Da quoted in Matthew (1979).
Table 1. Hybridization studies against 17 plasmid-encoded β-lactamases

*E. coli* C600 carrying the plasmid indicated was hybridized with either the 35S-labelled, or the biotin-labelled, Shv-1 probe. +, Positive hybridization signal; −, no hybridization; (−), hybridization signal with lower stringency post-hybridization washes.

Construction of Shv-1 gene probe

In view of our results that the Shv-1 gene accounts for more than 80% of the DNA in the 900 bp *PstI* fragment of pUB8 (Fig. 1), we decided to use this fragment purified from the high-copy-number recombinant plasmid pUB17 as a hybridization probe. Since there is the possibility of false hybridization signals from transposon-like sequences located adjacent to the Shv-1 gene, a situation previously encountered with a gene probe against the Tem-1 β-lactamase (Cooksey et al., 1985), we determined the specificity of the Shv-1 gene probe against plasmid preparations made from 17 *E. coli* C600 cultures carrying different plasmid-coded β-lactamases (Jacoby & Sutton, 1985). Although 32P is routinely used as the label for hybridization probes in research laboratories, and has been used to label a Tem-1 gene probe for clinical use (Ouellette et al., 1987), we feel that most laboratories will be unable to use 32P-labelled probes because of the considerable regulatory and practical problems associated with high-energy isotopes. For this reason we decided to label the Shv-1 probe with the lower-energy isotope 35S and with photobiotin.

The results showed, at the high stringency used for the post-hybridization washes, both the 35S- and the biotin-labelled probe only hybridized with the R1010 plasmid (Table 1). If the post-hybridization washes were done with 2 × SSC/0-1% SDS at 42 °C, then a signal was seen with the plasmids encoding the Lcr-1, the Cep-1 and the Oxa-2 β-lactamases with the 35S-labelled probe, and with the Oxa-2 plasmid when using the biotin-labelled probe. We believe that the difference between the two reflects the difference in sensitivity between radioactively labelled and biotin-labelled probes. These results imply some degree of homology between the probe DNA and a nucleotide sequence on these plasmids, though the homologous sequence may not, of course, be the coding region of the β-lactamase. We are investigating the degree of homology between these β-lactamases by molecular cloning and DNA sequencing.

The Shv-1 gene probe also gave hybridization signals against plasmids present in three clinical isolates of *E. coli*, which had been shown by isoelectric focussing to produce the Shv-1 β-lactamase, and with chromosomal DNA from 13 out of 14 clinical isolates of *Klebsiella pneumoniae* (Bisessar, 1986). This last result provides support for the suggestion that the Shv-1 gene evolved from the chromosomal β-lactamase of Klebsiella (Nugent & Hedges, 1979). No hybridization signals were seen with 20 clinical isolates which produced β-lactamases other than Shv-1.

Conclusions

We have demonstrated a method for the preparation of a specific Shv-1 β-lactamase gene probe which does not rely on nucleotide sequencing data. It has been reported that the sensitivity of detection of biotin-labelled probes is a factor of 4-8 lower than that of equivalent...
32P-labelled probes (Bialkowska-Hobrzanska, 1987). It is apparent from our study that the sensitivity of the biotin-labelled Shv-1 probe is sufficient for clinical use. In our experience, the relative advantages and disadvantages of using radioactively labelled or biotin-labelled probes are as summarized in Table 2. A radioactively labelled gene probe against the Tem-1 β-lactamase has been used to screen 328 clinical isolates for the presence of the Tem-1 gene and the results compared with isoelectric focussing (Jouvenot et al., 1987). The results obtained with both methods were concordant in 92.7% of the isolates. These authors hybridized their probe with colonies growing directly on nitrocellulose filters placed on MacConkey agar plates. This removes the need for the preparation of cell lysates and allows the screening of a large number of colonies; however, the total time before obtaining a result is 3 days.

One potential problem with the use of an Shv-1 probe for direct colony blotting is that this method cannot readily distinguish between plasmid or chromosomally encoded β-lactamase genes, whereas the resulting phenotype, in terms of the level of β-lactam resistance, may be considerably different due to the gene dosage effect. It may therefore be necessary to construct oligonucleotide probes specific for the two genes. A biotin-labelled probe has been used directly with colonies growing on agar plates to detect enteroinvasive E. coli. In order to prevent nonspecific hybridization signals extensive treatment of the hybridization filters with proteinase K was required before hybridization (Sethahut et al., 1985). Compared with antibiotic sensitivity testing β-lactamase gene probe technology therefore appears to offer little to assist rational therapy; however, it would obviously generate considerable information of great value for epidemiological investigations. The combined value of antibiotic sensitivity data, β-lactamase gene probe data and species identification would be of great value in generating a data base of information with considerable predictive value for antibiotic therapy.

We wish to acknowledge the financial support and facilities offered by Pfizer, Sandwich, UK, and for the constructive advice and criticism of this work offered by Brian Moore. U.B. was the recipient of an SERC CASE studentship.
