Mechanism of Gliotoxin Action and Factors Mediating Gliotoxin Sensitivity

By RICHARD W. JONES* AND JOSEPH G. HANCOCK

Department of Plant Pathology, 147 Hilgard Hall, University of California, Berkeley, CA 94720, USA

(Received 16 December 1987; revised 4 March 1988)

Resistance to the low $M_r$ fungal epitopoliketopiperazine toxin, gliotoxin, varied threefold between the phytopathogens Pythium ultimum and Rhizoctonia solani. Uptake of radiolabelled gliotoxin was rapid and concentration dependent. Uptake by P. ultimum was largely complete within 1 min while the rate of uptake peaked within 10 min for R. solani (anastomosis groups 2-2 and 4). Uptake of gliotoxin by P. ultimum was twice that shown by the more resistant R. solani. A deep rough mutant of Salmonella typhimurium, deficient in outer-membrane polysaccharide synthesis, was hypersensitive to gliotoxin, indicating that diffusion barriers play a role in relative sensitivity to gliotoxin. Fungal glutathione levels (reduced and oxidized) did not differ appreciably before or after gliotoxin exposure, indicating that this cytoplasm-based detoxification mechanism was not important in the relative fungal sensitivity to gliotoxin. Binding of the radiolabelled thiol reagents N-ethylmaleimide (NEM) and p-chloromercuribenzoic acid to fungal thiol groups was inhibited by gliotoxin. Conversely, the thiol reagents NEM and p-chloromercuribenzoic acid inhibited the uptake of radiolabelled gliotoxin. Uptake of radiolabelled amino acids and glucose was reduced by up to 85% by gliotoxin (8 $\mu$g ml$^{-1}$). It is suggested that the primary mechanism of action of gliotoxin involves selective binding to cytoplasmic membrane thiol groups.

INTRODUCTION

The epithiodiketopiperazine toxins (EPTs), which include the compounds gliotoxin, gliovirin, chetomin and sporidesmin, are produced by numerous fungi (Taylor, 1971; Leigh & Taylor, 1976; Howell & Stipanovic, 1983). They are characterized as low-$M_r$, nonpolar molecules with a bridged polysulfide region which confers activity. These compounds possess a broad spectrum of activity including inhibition of fungi, bacteria and viruses. Recent work has shown that gliotoxin also inhibits macrophage adherence (Mullbacher & Eichner, 1984).

EPT exposure generally results in a cellular stasis as opposed to a lethal response. EPTs have been found to induce mitochondrial swelling (Hadler et al., 1973; Middleton, 1974a), inhibit protein and nucleic acid synthesis (Kerridge, 1958) and also inhibit viral RNA-dependent RNA polymerase (Miller et al., 1968; Ho & Walters, 1969). EPT activity can be abolished by treatment with reducing agents such as glutathione and dithiothreitol (Cavallito et al., 1946; Trown & Bilello, 1972; Middleton, 1974b), indicating the importance of the epithio-region in toxicity, and suggesting that inhibitory activity is based upon blocking thiol regions of various intracellular proteins.

Current interest in the biological control of fungal plant pathogens has resulted in the release of EPT-producing fungi for this purpose. An understanding of the specific mechanisms of EPT-induced suppression, and factors regulating EPT sensitivity, is needed to evaluate the potential...
effectiveness of EPT-mediated biological control as well as the potential toxicological effects of EPT production.

In this study we report the effect of cellular diffusion barriers on the uptake of gliotoxin and the role of these barriers in the relative sensitivity to gliotoxin. Additionally, we report on the effect of gliotoxin on uptake of radiolabelled substrates and thiol reagents, and the response of intracellular glutathione levels after exposure to gliotoxin, in an attempt to determine the primary site of gliotoxin activity among fungi.

METHODS

**Isolates.** Cultures of *Rhizoctonia solani* Kuhn [isolates 2201 and 4001, anastomosis groups (AGs) 2-2 and 4 respectively] and *Pythium ultimum* Trow (ATCC 32939) were maintained on a synthetic liquid medium plus agar. *Salmonella typhimurium* isolates LT2 (wild-type) and 1181 (deep rough Rd2) (Nikaido, 1976) were maintained on nutrient agar. The deep rough isolate is deficient in production of the polysaccharide fraction of the lipopolysaccharide outer membrane, except for the heptose portion.

**Cultural conditions.** Fungi were grown on synthetic liquid medium (SLM), composition: (g l⁻¹), D-glucose, 6.0; DL- asparagine, 1.5; KH₂PO₄, 0.25; and (ml l⁻¹), 0.5 M-CaCl₂, 1.0; 1 mM-ZnCl₂, 1.0; 1 mM-MnCl₂.4H₂O, 3.0; 1 mM-MgCl₂.6H₂O, 2.0; 1 mM-FeNaEDTA, 4.0; 0.1 M-Na₂S₂O₃, 5H₂O, 5.0; 6 mM-thiamine. HCl, 2.0. The medium was buffered with 0.1 M-sodium phosphate (pH 5.8).

Petri dishes (100 x 15 cm) containing 20 ml SLM were inoculated with a small plug of mycelium and incubated for 2-3 d until the mycelial mat diameter was half that of the Petri dish. The fungal mats were then harvested, rinsed with sterile medium and placed in 50 ml fresh medium contained in a Waring blender. The mycelium was blended at low speed for 20 s. Suspensions of hyphal fragments (0.5 ml for *R. solani*, 0.25 ml for *P. ultimum*) were pipetted into individual Petri dishes containing 20 ml fresh SLM and incubated for 3 d at 26 °C. Cultures prepared in this manner provided consistent, uniform mycelial mats from which discs could be excised for experiments.

**Sensitivity of fungi to gliotoxin.** Gliotoxin (gift from S. J. Lucania, E. R. Squibb Co., Princeton, New Jersey, USA) was dissolved in methanol (2 mg ml⁻¹) and added to Petri dishes (60 x 15 cm), containing 7 ml SLM, providing concentrations of 1, 2, 4, 8 and 16 µg ml⁻¹. Methanol levels were equalized in all treatments and in the control dishes. Discs (3 mm diameter) were excised from the mycelial mats and transferred to individual Petri dishes. Each experiment, which included four plates for each treatment, was repeated twice. Cultures were incubated for 4 d in the dark then harvested, and the dry matter determined after drying to constant weight at 85 °C.

**Sensitivity of *S. typhimurium* to gliotoxin.** Cultures of strains LT2 and 1181 were grown for 6 h (37 °C, 200 r.p.m.) in covered test tubes containing Luria broth (g l⁻¹: tryptone, 10.0; yeast extract, 5.0; MgSO₄.7H₂O, 0.25). Samples of each culture (6.5 ml) were transferred to sterile tubes and the volume brought to 5 ml with fresh Luria broth. Initial bacterial populations were determined by dilution plating. Gliotoxin was added to a final concentration of 1.5 µg ml⁻¹ for tubes containing strain 1181 and to 30 µg ml⁻¹ for tubes containing strain LT2. Cultures were incubated in the dark in an incubator shaker for 24 h after which time the turbidity was measured (OD₆₅₀) for evidence of bacterial growth.

**Production of radiolabelled gliotoxin.** Three Petri dishes containing 20 ml gliotoxin medium (composition: (g l⁻¹), D-glucose, 15.0; (NH₄)₂SO₄, 2.0; KH₂PO₄, 0.5; MgSO₄.7H₂O, 0.25) were inoculated with approximately 3 x 10⁴ conidia of *Penicillium terikowsski* Zaleski (NRRL 2067). After 48 h incubation (26 °C), 2 µCi L-[U-¹⁴C]phenylalanine (495 mCi mmol⁻¹, 1.83 GBq mmol⁻¹) was added to each culture. After 7 d the culture filtrates were collected by vacuum filtration through Whatman no. 1 filter paper, and extracted with two 1/10 vols chloroform/water. The chloroform fraction was centrifuged for 5 min (17300 g) and collected, then dried in vacuo. The residue was resuspended in 1 ml ethanol, then transferred to sheets of silica gel (Eastman Kodak Chromagram uv 254). The sheets were resolved in chloroform/acetone (? 3:7, v/v) and visualized with short-wave UV. The region co-migrating with a gliotoxin standard was scraped from the sheets and eluted in vacuo.

**Fungal uptake of radiolabelled gliotoxin.** Three discs (15 mm diameter) from mycelial mats of each fungus were rinsed with sterile distilled water and transferred to individual Petri dishes (60 x 15 mm) containing 7 ml SLM. Two series of experiments were done. In the first radiolabelled gliotoxin was added at concentrations of 2.5 and 500 µg ml⁻¹ and the discs were removed from the medium after 10, 20 and 30 min incubation. In the second experiment, radiolabelled gliotoxin was added at the single concentration of 3.9 µg ml⁻¹ and the discs were removed at time intervals of 1, 3 and 5 min. In all cases, the discs were then rinsed with fresh liquid medium containing 5 mM unlabelled gliotoxin, transferred to vials containing 10 ml scintillation fluid and counted for
Antibiotic activity of gliotoxin

Sensitivity to gliotoxin

The inhibitory activity of gliotoxin is known to be biomass dependent (Brewer et al., 1966), therefore our values are expressed in terms of biomass. The minimum level of gliotoxin in the
medium at which growth of the phytopathogenic fungi was completely inhibited was [(mg fungal dry wt)\(^{-1}\): P. ultimum, 9-3 \(\mu\)g ml\(^{-1}\); R. solani 2201, 17-5 \(\mu\)g ml\(^{-1}\), and R. solani 4001, 27-0 \(\mu\)g ml\(^{-1}\). The variation is significant when considering the limited level of gliotoxin available in the soil (Wright, 1952). These levels were fungistatic but not fungicidal. Growth of the deep rough mutant of S. typhimurium (1181) was prevented at 24 h when inoculum levels were below 2.0 \(\times\) 10\(^6\) cells per 5 ml broth containing 1.5 \(\mu\)g gliotoxin ml\(^{-1}\). Growth of the wild-type S. typhimurium (LT2) was prevented at 24 h when inoculum levels were below 1.5 \(\times\) 10\(^4\) cells per 5 ml broth containing 3.0 \(\mu\)g gliotoxin ml\(^{-1}\). The wild-type was over 13-fold less sensitive even though it was exposed to twice the gliotoxin concentration of the deep rough mutant.

**Uptake of radiolabelled gliotoxin**

Radiolabelled gliotoxin was isolated from culture filtrates of P. terlikowskii and purified to a specific activity of 1464 d.p.m. (\(\mu\)g gliotoxin)\(^{-1}\). Incorporation was approximately 2-1%. When the radiolabelled gliotoxin was added to SLM containing the test fungi, its uptake was rapid and concentration dependent (Figs 1 and 2). The rates varied considerably between the fungi. Uptake by P. ultimum was largely completed in less than 1 min, whereas the isolates of R. solani took at least 10 min to approach the maximum binding. The amount of uptake also differed, with P. ultimum and R. solani 2201 taking up over twice the amount of gliotoxin than was taken up by R. solani 4001. Unlabelled gliotoxin interfered with uptake of radiolabelled gliotoxin, indicating that they had the same binding site.

Interaction between thiol reagents and gliotoxin

The organisms varied in their uptake of radiolabelled gliotoxin in the presence of thiol reagents (Table 1). The permeant NEM reduced gliotoxin uptake by 66%, 61% and 82%, respectively, for *P. ultimum*, *R. solani* 2201 and *R. solani* 4001. The nonpermeant PCMBA reduced gliotoxin uptake by 5%, 30% and 0%, respectively, for the same fungi at the end of a 10 min incubation. The two compounds differ in reactivity: NEM binds to internal and external thiol groups, while PCMBA generally reacts only with external thiol regions. That they both inhibit gliotoxin uptake indicates that gliotoxin is binding to various thiol regions accessible to both NEM and PCMBA. Preliminary studies showed that gliovirin, sodium nitrite and various dipeptides did not interfere with gliotoxin uptake, indicating preferential binding sites between each of the tested compounds. Gliotoxin was able to reduce the binding of radiolabelled thiol reagents (Table 2). Pre-incubation with gliotoxin resulted in 28%, 8% and 24% reductions in binding of [3H]NEM by *P. ultimum*, *R. solani* 2201 and *R. solani* 4001. Gliotoxin reduced iodo[3H]acetic acid binding by 43% for *P. ultimum*. Iodo[3H]acetic acid binding was very low for the other fungi even in the absence of gliotoxin.

Effect of gliotoxin on uptake of radiolabelled substrates

The simultaneous incubation of gliotoxin with radiolabelled substrates resulted in a marked decline in their uptake (Table 3). Uptake of L-arginine was reduced by 85% for *P. ultimum* and
Table 4. Effect of gliotoxin on intracellular levels of fungal glutathione

Mycelial discs were incubated in glucose/asparagine liquid medium with 10 μg gliotoxin ml⁻¹ for 1 h. Glutathione was assayed spectrophotometrically with o-phthalaldehyde as detailed in Methods. Values are expressed as pmol (mg mycelial dry wt)⁻¹ and are the means of four replicates; SEM values are given in parentheses.

Uptake of L-phenylalanine was reduced by 60%, 30% and 67%, respectively, for *P. ultimum*, *R. solani* 2201 and *R. solani* 4001. Uptake of D-glucose was reduced by 28%, 38% and 16% for the same fungi.

Initial glutathione levels did not correlate with the observed variations in fungal sensitivity to gliotoxin. There were also no appreciable changes in the levels of reduced glutathione (GSH) after exposure of mycelia to gliotoxin (Table 4). Interactions between GSH and gliotoxin can occur during the extraction process and could account in part for the slight decline in GSH levels. Levels of oxidized glutathione (GSSG) declined slightly. This may represent GSSG reductase activity, but the contribution to the GSH pool would be minimal given the magnitude of GSSG depletion. This evidence suggests either that gliotoxin does not enter the cytoplasm or that glutathione does not react with gliotoxin in the cytoplasm. In either case glutathione would not play a role as a detoxicant for gliotoxin resistance.

DISCUSSION

The variation in the uptake of gliotoxin by the fungi studied here correlates in part with their observed sensitivity to gliotoxin. The uptake is concentration dependent and levels off within 10 min. The kinetics imply a passive, adsorptive process. The same observation has been made for the uptake of sporidesmin by rumen protozoa (Shaw & Wright, 1972). The role of diffusion in uptake of gliotoxin is also seen with *S. typhimurium* mutants, where defects in production of the polysaccharide region of the outer membrane (Nikaido & Vaara, 1985) result in large increases in sensitivity to gliotoxin. The sensitivity to gliotoxin of a Gram-negative bacterium, deficient in production of outer membrane polysaccharide, suggests that the relative gliotoxin sensitivity among micro-organisms may be a reflection of the ability of gliotoxin to reach sensitive cellular sites. It also indicates that there are cellular sites which are sensitive to gliotoxin among Gram-negative bacteria.

Moderate levels of resistance to gliotoxin were previously obtained for *Staphylococcus aureus* (Klimek et al., 1948) and *Bacillus subtilis* (Brewer et al., 1967) after repeated subculturing (30–80 transfers) on gliotoxin-amended medium. The resistance was lost after culturing the bacteria on gliotoxin-free medium. It is known that the cell-wall hydrophobicity changes after repeated subculturing and, given the selection pressure of a hydrophobic antibiotic, the cells might be selected for reduced permeation of the antibiotic, which could be accomplished through reduced cell-wall hydrophobicity.

The structure and composition of fungal cell walls is not as well characterized as the outer membrane of Gram-negative bacteria. It is likely that adaptations in structure and composition have been selected for based upon the particular environment in which the organism exists (Cook & Baker, 1983). *P. ultimum* is a rapid growing primary colonizer of fresh organic matter. Its hyphal walls would be expected to be quite permeable to allow for rapid diffusion of low-Mᵣ nutrients to support rapid growth. It is, however, highly susceptible to antibiosis, with survival...
Antibiotic activity of gliotoxin

between periods of fresh organic matter occurring through production of sporangia and oospores (Stanghellini & Hancock, 1971). \textit{R. solani} colonizes organic matter later than \textit{P. ultimun}; it grows more slowly but has a higher competitive saprophytic activity (Papavizas, 1964). The saprophytic activity varies between AGs of \textit{R. solani}. \textit{R. solani} AG 2-2 has the more limited saprophytic capability. It produces abundant sclerotia and generally attacks plants aerially or near the soil surface, thus it has limited exposure to antibiotic-producing organisms. \textit{R. solani} AG 4 has stronger saprophytic abilities than AG 2-2 and is more resistant to inhibitory compounds. \textit{R. solani} apparently employs its cell wall as a diffusion barrier which allows for growth under harsher environmental conditions; this is similar to enteric bacteria which employ their outer membrane as a permeability barrier.

Biological control of phytopathogenic fungi may be limited by the architecture and chemical composition of cell walls of the target organism. We have shown that the walls can mediate the diffusion of hydrophobic antibiotics such as gliotoxin. One means of overcoming this barrier would be mycoparasitism, where degradation of the cell wall could allow for passage of the antibiotic. This would not be effective in systems where rapid pathogen control is desired, such as protection of seeds and seedlings; however, it may play a role in the long-term reduction of pathogen inoculum.

The blocking of membrane thiol groups by gliotoxin evidently accounts for its broad-spectrum activity. It provides a highly effective means for producer organisms to compete with and/or displace other organisms. This could explain why a number of soil-borne fungi have the ability to produce gliotoxin and related compounds (Taylor, 1971). The broad-spectrum, nonspecific, moderately toxic activity of gliotoxin suggests that resistance will not readily arise.

Under the nutrient-limited conditions prevalent in many soils it is expected that microorganisms depend on high permease activity. Many permeases are sensitive to thiol reagents (Nelson \textit{et al}., 1975). Also, fungal propagules often depend upon exogenous nutrients to induce germination. Interference with these nutrient uptake mechanisms could rapidly lead to nutrient-dependent fungistasis. Our studies were done at gliotoxin concentrations similar to those levels detected in the soil (Wright, 1952), therefore it is likely that our results reflect events which could actually occur in the soil. The nutrient limiting activity of gliotoxin suggests that its efficacy will be reduced in soils with high levels of organic matter and on root surfaces, where nutrients would be less limiting.

The variation in sensitivity to EPTs among micro-organisms may also be due to the susceptibility of target sites on their cell membranes. The membrane transport capabilities have been shown to differ between isolates of \textit{R. solani} (Lin & Gottlieb, 1974). The variation in competition between thiol reagents and gliotoxin, depending on the test fungus, suggests that the availability of the target sites differs between organisms. The same has been observed for other membrane thiol binding compounds (Cunningham \textit{et al}., 1979; Morris \textit{et al}., 1984). Previous work on the mode of action of EPTs did not study the effects on membrane thiol groups. Kerridge (1958) found that gliotoxin (30 \(\mu\)g ml\(^{-1}\)) prevented incorporation of glycine into proteins and nucleic acids but did not determine if the isotope-labelled glycine was initially taken up by the test organism, \textit{Saccharomyces carlsbergensis}, after exposure to gliotoxin. The secondary effects of membrane thiol group inhibition can be misinterpreted as the primary cellular response. For example, cytochalasin A or sodium nitrite exposure results in multiple alterations of cellular physiology but their primary mechanism of action is binding to membrane thiol groups (Cunningham \textit{et al}., 1979; Morris \textit{et al}., 1984).

The suggestion that swelling of isolated, gliotoxin-treated mitochondria was due to a reaction with thiol groups of mitochondrial membrane proteins (Hadler \textit{et al}., 1973; Middleton, 1974b) was probably accurate; however, this does not appear to be the initial site of EPT activity. Reaction with mitochondria may not even occur \textit{in vivo} except possibly at high EPT levels, as there is no evidence that EPTs at low dosages enter the cytoplasm at significant concentrations. In our experiments intracellular glutathione status did not change in the presence of gliotoxin, which provides support for the idea that gliotoxin does not initially enter the cytoplasm. Glutathione levels were assayed after 1 h of exposure to gliotoxin while the majority of gliotoxin uptake is complete within 10 min. Gliotoxin and glutathione react spontaneously, without the
need for glutathione transferase activity, so interference with this enzyme would not account for a lack of glutathione depletion. Another EPT, sporidesmin, was also found not to accumulate in the cytoplasm of protists (Shaw & Wright, 1972).

It is possible that reactions with membrane thiol groups can lead to increased membrane permeability by affecting the orientation of the membrane proteins. In this study we did not determine whether leakage occurred. We would expect, however, based upon the fact that glutathione levels were not significantly altered, that membrane leakage was not occurring. Also, Mullbacher et al. (1985) found that inhibition of macrophage adherence, after treatment with gliotoxin, was not accompanied by alteration in the permeability of the macrophage membrane. Our data, showing interference with membrane thiol regions, suggest that the same mechanism may be involved in the inhibition of macrophage adherence. Cellular adhesion can be inhibited by thiol reagents (Grinnell & Srere, 1971).

Evidence for in situ production of gliotoxin in lung tissue infected with Aspergillus fumigatus has not been shown. If gliotoxin is in fact produced in situ, then it would be interesting to determine its effect on another lung-infecting fungus, Histoplasma capsulatum. The temperature-dependent conversion of H. capsulatum from a mycelial stage to the infective yeast stage can be irreversibly blocked by thiol-reactive compounds (Medoff et al., 1986). It would also be interesting to determine whether gliotoxin-mediated plant disease suppression is, in part, due to plant phytoalexin induction, as phytoalexin production can be induced by compounds reacting with membrane thiol groups (Gustine, 1987).

The information provided by this study should prove useful in understanding the mechanisms mediating the control of plant disease through introduction of EPT-producing organisms to the soil. Additionally, this information should prove valuable in toxicological studies which are required before registration of EPT-producing organisms as commercial biological control agents.
