(Received 28 October 1988; revised 28 March 1989; accepted 26 April 1989)

Addition of competence factor extracts to trigger competence in a culture of *Streptococcus pneumoniae* induced an increase in the intracellular pH and the Na⁺ content of the bacteria without any change in the K⁺ pool or in the membrane potential. These ionic shifts were concomitant with a stimulation of glycolysis that resulted in an enhanced ATP pool. Thus, in transforming conditions, at extracellular pH 7.8, competent bacteria presented a particularly high energetic state resulting from an increase in ΔpH and in the ATP pool, associated with an enhanced Na⁺ content. These features are discussed in the context of homeostasis regulation in response to an environmental stimulus.

INTRODUCTION

Competence for genetic transformation in *Streptococcus pneumoniae* is a transitory physiological state controlled by an exported activator 'competence factor', CF (Pakula & Walczak, 1963; Tomasz & Hotchkiss, 1964; Tomasz & Mosser, 1966; Leonard & Cole, 1972), whose target is likely to be on the surface of the bacteria, i.e. on the cell wall and/or on the cytoplasmic membrane (Ziegler & Tomasz, 1970; Kohoutova, 1973; Horne et al., 1977).

During development of competence, a transient increase in the initial rate of isoleucine uptake, with an optimum at the peak of culture transformability is observed (Trombe, 1983). In our strains of *S. pneumoniae* a single transporter coupled to the protonmotive force (Δp) has been described for isoleucine and the maximum transport velocity, V, is modulated by the value of Δp (Trombe et al., 1984). Therefore, variations of the initial rate of isoleucine uptake at competence are likely to reflect modulation of Δp resulting from modulation of ionic fluxes during competence development. Changes in ionic fluxes are observed in other pleiotropic responses to environmental conditions such as osmoregulation in *Escherichia coli*, which involves K⁺ regulation (Laimins et al., 1981; Meury & Kepes, 1981). In the anaerobic bacterium *S. pneumoniae* ATP derived from glycolysis is the chief energy donor for the generation of ionic gradients via cation ATPases (Heefner & Harold, 1982; Kakinuma & Harold, 1985; Rosen, 1987). In this paper, the ATP content and the size of ion pools during competence development after stimulation by CF are described.

METHODS

Chemicals. Nutrients used for growth media were from Difco; other reagents were of analytical grade. Monensin was provided by Lilly Research, Surrey, UK, and 3,3',4',5-tetrachlorosalicylanilide (TCS) by Dr I. R. Booth, University of Aberdeen, UK.

Abbreviations: pHᵅ, extracellular pH; pHᵃ, intracellular pH; Na⁺, extracellular sodium concentration; Na⁺ᵅ, intracellular sodium concentration; TCS, 3,3',4',5-tetrachlorosalicylanilide; CF, competence factor; Δpᵅᵅᵅ, electrochemical potential difference for protons; Δψ, electric transmembrane potential; ΔpH, pHᵃ − pHᵅᵅᵅ, i.e. the proton chemical gradient; F, Faraday's constant; Z, 2·3RT/F = 59 mV at 25 °C.

Organism, growth media and competence development. The experiments were done with *S. pneumoniae* strain CP 1000 (Morrison *et al.*, 1984), which exhibits a wild-type phenotype for genetic transformation.

Bacteria were routinely induced to competence as described by Morrison *et al.* (1984). Briefly, stock cultures were grown at pH 7.5 in a complex medium containing (g l⁻¹): NaCl, 5; yeast extract, 1; tryptone, 5; enzymic casein hydrolysate, 10; glucose, 2; K₂HPO₄, 3. When the culture reached an OD₄₀₀ of about 0.4, glycerol (15% v/v) was added and samples were kept frozen at −80 °C. To obtain precompetent bacteria, samples were thawed and diluted 1 in 100 in standard growth medium, adjusted to pH 7 and enriched with CaCl₂ (1 mM) and bovine serum albumin (2 mg ml⁻¹), and were grown for 2 h at 37 °C. Such cultures constituted the tester cells; when shifted to pH 7.8 they were activatable by 1–5% (v/v) of a crude preparation of CF or by 0.1–0.5% of a partly purified extract of CF obtained by (NH₄)₂SO₄ fractionation at pH 11. As the incubation time required to reach competence depends on parameters such as the culture density and the CF preparation, competence tests were routinely done in parallel with other measurements. Competence was monitored by assaying the appearance of DNA-degrading activity and by biological transformation tests. Selection of transformants for a given genetic marker after incubation with DNA was done as described by Morrison *et al.* (1984). Briefly, an appropriate dilution of the cell suspension that had been incubated with DNA bearing a genetic marker (ami) conferring methotrexate resistance (MtxR) was plated on blood-agar medium and incubated for 2 h at 37 °C. A layer of agar containing the selective agent (10⁻³ M-methotrexate) was added and incubation continued. The number of colony forming units (c.f.u.) was determined after 18 h. The frequency of transformants was calculated as the ratio between the numbers of c.f.u. obtained in the presence and in the absence of the selective agent. Under our experimental conditions the number of spontaneous mutants never exceeded 1% of the number of transformants.

For NMR experiments, 500 ml of an early exponential phase culture, or 3 l of a culture induced to competence, was centrifuged at 4 °C, washed with the buffer required for the NMR experiment, and concentrated in 1 ml of that buffer at 4 °C. Competence tests and readings for NMR spectra (2–8 min accumulated free induction decay) were done immediately.

The medium used for NMR was derived from a classical mineral medium used for growth of *S. pneumoniae* (Trombe *et al.*, 1984). This medium allowed competence expression of induced bacteria but not competence induction: as far as could be determined, at least concerning competence, the physiological state of the culture at the time it was harvested for NMR measurements did not change during the experiment. The medium contained: Tris, 40 mM, NH₄Cl, 52 mM, KCl, 7.5 mM, MOPS, 20 mM. The pH and the NaCl concentration were adjusted as required. Osmolarity was maintained at 240 mosM by addition of KCl.

Internal pH (pHᵢ). (a) ³¹P NMR combined with TCS treatment. The chemical shift of the inorganic phosphate peak can be taken as an indicator of the pHᵢ value; this allows one to ignore eventual differences between the internal volume of bacteria in different physiological states (Ogawa *et al.*, 1981; Slonczewski *et al.*, 1981; Booth, 1985). Indeed, for a given temperature, pHᵢ can be related to a Henderson–Hasselbach-type equation (Ogawa *et al.*, 1981; Lachmann & Schnackerz, 1984). When based on ³¹P NMR, the method is limited to a pH range determined by the pKᵢ of inorganic phosphate, the value of which depends on the ionic strength of the cytoplasm (Ogawa *et al.*, 1981). The chemical shift of the ³¹P resonance is also influenced by the paramagnetic ionic content of the cells (Essa *et al.*, 1983) and may vary between cultures. Therefore, pHᵢ was deduced from the external pH (pHₑ) by means of a ‘null-point’ method after treatment of the bacteria with the protonophore TCS at different values of pHₑ. TCS collapses the protonmotive force, i.e. Δψ and ΔpH. The remaining Donnan potential, which was about 11 mV in our experimental conditions, was constant throughout the experiment. Thus pHₑ values estimated experimentally might differ from the real values by 0·1 pH unit. ³¹P NMR measurements were done at 121·5 MHz on a Bruker AM 300WB instrument, using the standard 10 mm ³¹P probe kept at 5 °C by a stream of nitrogen. Experiments were done in flat-bottomed tubes, and the sample volume was adjusted to 2·3 ml. Bi-level high-power proton decoupling was used to remove ¹H–³¹P dipolar coupling (0·3 W between pulses and 4 W during data acquisition). Sample spinning was used to improve the resolution. Spectra were accumulated in 100–400 transients without T lock using 7 µs (60°) pulses, an interpulse delay of 1·64 s, a sweep width of 10 kHz and 16K data points. An exponential multiplication corresponding to 80 Hz line-broadening was applied to the free induction decay to increase the signal-to-noise ratio and was zero-filled behind the Fourier transformation. Spectra were obtained after 2–8 min. NMR peak positions in spectra were given in parts per million (p.p.m.) from the peak position of 85% orthophosphoric acid as an external reference. The peaks were identified by their chemical shift. The assignments were confirmed by addition of the corresponding commercial compounds. For null-point determination, a ³¹P NMR spectrum was obtained (Fig. 1) at a given pHₑ and then TCS (1 µmol per 5 × 10¹⁰ bacteria) was added and a second spectrum was obtained. The displacement of the chemical shift (δ) of the phosphate resonance (³¹P) induced by the protonophore was measured (Δδ). An example is given in Fig. 2. The peak corresponding to inorganic phosphate was followed specifically because of its better resolution compared to the others. The null-point corresponds to conditions where Δδ was not significant.

(b) ΔpH determination by [¹⁴C]benzoic acid accumulation. [¹⁴C]Benzoic acid accumulation was determined as described previously (Trombe *et al.*, 1984), assuming an intracellular volume of 0·96 µl per 10⁸ bacteria (Trombe *et al.*, 1984). The pHᵢ was deduced from pHₑ measurement and ΔpH calculation using steady-state accumulation of the probe.
Determination of the internal Na⁺ concentration (Na⁺ᵣ). (a) ³¹P NMR combined with monensin treatment. Na⁺ᵣ was deduced from Na⁺ by means of a null-point method after treatment of the bacteria at different Na⁺ᵣ values with monensin, an ionophore that exchanges monovalent cations for H⁺ with a high specificity for Na⁺. Indeed, such a specificity was clear in our experiments where the pHᵢ shift induced by monensin addition responded to ΔpNa⁺ rather than ΔpK⁺ (see Tables 2 and 3). The operations were the same as for pHᵢ determination using ³¹P NMR. An initial ³¹P NMR spectrum was obtained at a given Na⁺ᵣ value, then monensin (1 µmol per 5 × 10¹⁰ bacteria) was added and a second spectrum was obtained. The displacement of the chemical shift (δ) of the phosphate resonance (³¹P) induced by monensin was measured (Δδ). In the presence of monensin, Na⁺ moves down its concentration gradient and the H⁺ moves in the opposite direction. The null-point corresponds to conditions where Δδ is not significant and indicates that Na⁺ᵣ = Na⁺.

(b) ²³Na NMR. ²³Na NMR measurements were done at 66-15 MHz on a Bruker WH 250 instrument using the standard 10 mm ²³Na probe kept at 5 °C by a stream of nitrogen. Experiments were done in flat-bottomed tubes and the volume of the sample, bacteria suspended in a Na⁺-free medium, was adjusted to 1-5 ml. Spectra were accumulated in 500 transients using 7 µs (90°) pulses, an interpulse delay of 3 s, a sweep width of 50 kHz and 16K data points. The instrument was calibrated using NaCl solutions of known concentration. Relative quantities of free or bound Na⁺ were evaluated either by measuring the areas of the peaks or by weighing after enlargement. Measurement accuracy was about ±10% for free Na⁺ and 50% for the bound form.

Flame photometry. For measurement of ion contents by flame photometry (Schultz & Solomon, 1961), 10 ml samples of a culture were quickly filtered on HA Millipore filters pre-rinsed with 100 ml (NH₄)₂SO₄. The bacteria were then washed with 2 ml of a solution of sucrose (500 mM) and the filters were eluted in 1 ml 1 M-HCl. Measurements were made using a Perkin-Elmer 290 B instrument. Control values were obtained by filtration of the culture medium; they never exceeded 20% of the sample value. Intracellular cation concentration was estimated assuming that 10⁸ bacteria represent an intracellular space of 0-96 µl (Trombe et al., 1984). The values presented are the means of four determinations on independent cultures. Each determination was the result of triplicate filtration assays on the same culture.

Glucose consumption. This was determined by measuring the amount of glucose present in the culture medium before and after bacterial growth using a commercial glucose oxidase/peroxidase system (Merck).

ATP and L-lactate determinations. These were done after perchloric acid extraction as described previously (Trombe et al., 1984). Briefly, 1 ml of a culture in the required physiological state was precipitated with 90 µl 70% (v/v) perchloric acid at 4 °C. After centrifugation, 900 µl of supernatant was withdrawn and neutralized with 215 µl of a solution containing 1-2 M-Tris, 0-175 M-KCl, 4 M-KOH. The sample was then centrifuged and the supernatant was kept frozen before ATP and L-lactate determinations. ATP was assayed by bioluminescence...
measurements using a luciferin–luciferase system (Lumit-PM). Calibration was by adding known amounts of ATP to the samples. For each sample ten determinations were made; the six to nine values closest to the mean were used. Standard deviations varied from 2 to 10% of the mean. The quantity of L-lactate produced during bacterial growth was determined using commercial L-lactate dehydrogenase from rabbit muscle.

$\Delta V$ measurement. This was done by measuring $[^{3}H]$tetraphenylphosphonium accumulation and using the Nernst equation as described elsewhere (Trombe et al., 1984).

RESULTS

Protonmotive force at competence

If not otherwise stated, measurements were made during competence development and more precisely at the peak time, when the frequency of competent bacteria in the population reached 0.9 as shown by transformation experiments using a cloned genetic marker (ami) (see Fig. 3).

In order to determine the reason for increased isoleucine transport at competence (Trombe, 1983) both components of the protonmotive force were measured. The value obtained for $\Delta \psi$ was 138 mV $\pm$ 5 mV, which is similar to previous determinations in these bacteria (Trombe et al., 1984). On the other hand, measurements using $[^{14}C]$benzoic acid gave a $\Delta p$H value of 0.5 at pH = 7.8, indicating a net alkalinization of the cytoplasm at competence since the control exhibited no $\Delta p$H in the same conditions, as already shown in S. pneumoniae (Trombe et al., 1984). This result was confirmed by the method combining $^{31}P$ NMR and TCS treatment (see Methods). TCS induced an acidification of the cytoplasm in the range of 7 < pHc < 8.2, with a null point between 8.2 and 8.4 in competent bacteria, while in the control the null point occurred at pHc = 7.9 (Table 1). It is important to note that, in competent S. pneumoniae, a $^{31}P$ NMR resonance shift after TCS addition was still observed at pHc = 8.2. According to several reports, the pK2 of inorganic phosphate is 6-8 at physiological ionic strength (Nicolay et al., 1981; Ogawa et al., 1981). Under these conditions, $^{31}P$ NMR resonance is invariant above pH 8. The shift, still observed at pHc = 8.2, suggests that, in S. pneumoniae, the pK2 of inorganic phosphate was more alkaline than in other neutrophilic bacteria studied (Nicolay et al., 1981; Slonczewski et al., 1981). It is possible that a more alkaline pK2 reflects a lower ionic strength of the cytoplasm of S. pneumoniae compared to other species. Unfortunately, we were unable to construct a titration curve in order to determine pK2, because the intracellular volume contribution to the total volume of a lysate could not exceed 10%, given the known intracellular space of the bacteria (0.96 µl for $10^8$ cells; Trombe et al., 1984).

Thus competent bacteria have a cytoplasm which is more alkaline than that of the controls, and as a consequence a higher $\Delta \mu_{\text{H}^+}/F$ resulting from an extra $Z\Delta p$H of 30 mV.

Na+ and K+ content at competence

The Na+ and K+ contents of the culture during the development of competence were measured by flame photometry. There was no significant variation in the K+ content of the culture, suggesting no specific regulation of K+ transport during competence as previously shown by Tomasz (1969) (Table 2). In contrast, the values for Na+ content fluctuated with a maximum around 340 mM before the start of competence (15 min after CF addition), 120 mM at the peak time and 86 mM at the end of the competence wave (Table 2). This last value was similar to that in the control (not shown).

These results were corroborated by determinations using a method where $^{31}P$ NMR and monensin treatment were combined. Monensin, an ionophore that exchanges H+ and cations with a high specificity for Na+, was expected to change pH, while it reduced $\Delta \mu_{\text{Na}^+}$. Thus, shifts in $^{31}P$ NMR displacement after monensin addition should reflect monensin-induced pH changes consequent upon the existence of a transmembrane Na+ gradient. In the absence of a Na+ gradient no change of pH should occur. Na+ may therefore be estimated from the Na+ value under conditions where no $^{31}P$ NMR resonance displacement was observed after monensin addition. The results of a typical experiment using non-competent bacteria (Table 3) showed that for Na+ values ranging between 1 and 60 mM the $^{31}P$ NMR peak shifted toward positive values after monensin addition, indicating an acidification of the cytoplasm. Time (min)

Fig. 3. ATP content of the culture during competence expression. Tester cells were incubated at 37 °C in the presence or in absence of CF (5%, v/v). At intervals, 1 ml samples were extracted for ATP determination (vertical bars: —, plus CF; ——, minus CF), and 0.1 ml samples were incubated for 5 min at 30 °C in the presence of pR172 DNA (0.1 µg ml⁻¹) bearing the *ami* marker. The frequency of Mtx⁸ transformants (○) was determined by plating (see Methods). ○, C.f.u. ml⁻¹ in the absence of CF; ●, c.f.u. ml⁻¹ in the culture induced by CF.

120 mM-Na⁺, the ³¹P NMR resonance peak shifted toward negative values, suggesting alkalinization of the cytoplasm. The null point (Na⁺ concentration equal in the intracellular and extracellular compartments) occurred at 85 mM-Na⁺ (Table 3). In contrast, when competent bacteria were used, the null point occurred at 120 mM (Table 3). These results were in good agreement with data obtained by flame photometry (Table 2); both approaches showed that competent bacteria had a greater Na⁺ pool than non-competent bacteria. Indeed, ²²Na transport measurements indicated a net uptake of Na⁺ in competent bacteria compared to controls (not shown).

Na⁺ can be free in the cytoplasm or it may be linked to macromolecular species as revealed by ²³Na NMR (Lazlo, 1978). ²³Na NMR of control and competent bacteria showed a similar partitioning of Na⁺, with a ratio of free Na⁺ to bound Na⁺ of about 0.7, suggesting no specific change in the distribution of the cation within the cytoplasm at competence.

In order to check the physiological significance of the observed modulation of Na⁺ transport during competence induction we used monensin at Na⁺ = 120 mM. A concentration as low as 2 µM-monensin totally inhibited competence induction without reducing cell viability. This suggests that a controlled Na⁺ circulation is determining induction.

**Competence cycle and the ATP pool**

ATP measurements in bacterial extracts prepared at different stages of competence expression showed that in competent bacteria the ATP pool reached 9.5 ± 0.5 mM while it was 6.3 ± 0.5 mM in the control (Fig. 3). This enhanced ATP content probably resulted from glycolytic stimulation; glucose consumption in competent cultures was 50% greater than that in control cultures (330 vs 220 µmol per OD₄₀₀ unit).

**DISCUSSION**

 Several independent methods showed an increased intracellular pH associated with an enhanced Na⁺ content of the bacteria at competence.
The results obtained by ΔpH determination using [14C]benzoic acid as a probe agreed well with those obtained by a combination of 31P NMR resonance and protonophore treatment at different pHv values. They indicated a net alkalinization of the cytoplasm in competent bacteria: the pHv of such cells reached 8.3, and created a ΔpH of 0.5 at pHv 7.8, while in the control, pHv was 7.8 and no ΔpH was measured, a result similar to previous findings (Trombe et al., 1984). No change in Δψ value was observed at competence, therefore the increased ΔpH might account for the increased rate of Δp-dependent isoleucine uptake in competent bacteria (Trombe, 1983).

Direct Na+ determinations by flame photometry corroborated results derived from a combination of 31P NMR and monensin utilization at different Na+ values. The Na+ value was about 120 mM in competent bacteria, compared to 85 mM in the control. This increase in Na+ was not followed by a change in the distribution of the cation within the bacteria as shown by 23Na NMR, a technique which allowed estimation of the ratio of free Na+ to bound Na+; this ratio was around 0.7 in both competent and control bacteria. Uptake experiments using 22Na suggested that this increase resulted from net uptake of Na+ (not shown). This increase in pHv and Na+ was not accompanied by variation of the K+ content of the bacteria during the competence cycle (Table 2). However, it was accompanied by a stimulation of glycolysis resulting in an enhanced ATP content during induction (Fig. 3).

It is possible that cytoplasmic alkalinization resulting from Na+/H+ exchange stimulated glycolysis (Moore et al., 1979). A Na+/H+ antiporter has been described in several bacteria, including E. coli (West & Mitchell, 1974; Bassilana et al., 1984). Activation of such a function at competence should increase pHv and Na+ and stimulate glycolysis, as already shown in some eukaryotic cells stimulated by insulin (Moore et al., 1979) or growth factors (Shuldiner & Rozengurt, 1982; Moolenar et al., 1983; Paris & Pouysségur, 1984; Metcalfe et al., 1985). However, such functioning of the Na+/H+ antiporter in eukaryotes is dependent upon the function has been proposed in S. faecalis (Kakinuma & Harold, 1985) but has yet to be established in S. pneumoniae. Homeostatic regulation in prokaryotes is more complex (Plack & Rosen, 1980; Kroll & Booth, 1981; Kobayashi et al., 1982; Booth, 1985), since pumps exchanging Na+/H+ (Heefner & Harold, 1982) and Na+/K+ (Kakinuma & Harold, 1985), as well as the Na+/H+ antiporter (West & Mitchell, 1974; Bassilana et al., 1984; Goldberg et al., 1987), contribute to the production of a Na+/Na+ gradient < 1 (Schultz & Solomon, 1961; Castle et al., 1986) while pHv seems to be regulated only by the F1F0 ATPase in streptococci (Kobayashi et al., 1982).

An increase in ATP produced by glycolysis was described in the SOS response in E. coli (Barbè et al., 1983) and an SOS-like system is induced at competence in Bacillus subtilis (Love & Yasbin, 1986). On the other hand, a similar response was obtained in S. pneumoniae in the late exponential growth phase (not shown). Thus the stimulation of glycolysis may constitute a metabolic response to some stress or and nutritional imbalance. At competence the regulation of Na+ fluxes appeared to be directly involved in the induction process since 2 μM-monensin, which tends to collapse ΔμH+, totally blocked induction without inhibiting growth. Moreover, cytoplasmic alkalinization at competence probably corresponds to optimal conditions for DNA uptake (Clavé et al., 1987). Experiments are now in progress to characterize the functions, probably under the control of competence activator, that are involved in such regulation.

We thank Dr I. R. Booth (University of Aberdeen, UK) for providing us with TCS, and for helping us prepare the manuscript.
