Evidence for the presence of two distinct membrane ATPases in 
*Spiroplasma citri*

(Received 5 July 1990; revised 3 September 1990; accepted 17 September 1990)

Triton X-100 (TX-100) extraction of *Spiroplasma citri* plasma membrane solubilized two types of ATPase differing in their pH of maximum activity. The activity measured at pH 8.5 was inhibited by vanadate and the activity measured at pH 6.5 was not. The vanadate-sensitive ATPase had a relatively basic isoelectric point (8.65) and therefore could be separated from the vanadate-insensitive ATPase using chromatofocusing. Elution of the TX-100 membrane extract in a pH gradient from 9 to 6 generated two peaks of ATPase activity: one in the acidic range, composed of an F,F₂-type ATPase, and one in the basic range, corresponding to the vanadate-sensitive activity. Electrophoretic analysis of proteins from the latter peak revealed one major polypeptide of 37 kDa. This peptide was shown to correspond to spot A37 in a two-dimensional protein map of *S. citri*. Using the gene for the *kdp*-operon of *Escherichia coli* as a probe in heterologous hybridization, sequences were detected in the genomic DNA of *S. citri*, suggesting that a gene coding for an enzyme related to this P-type ATPase is present in the *S. citri* genome. We therefore postulate the presence of two distinct kinds of ATPase in *S. citri*: one of the F-type which is resistant to vanadate inhibition, and one, probably of the P-type, which is vanadate-sensitive.

**Introduction**

Almost all bacterial ion-motive ATPases discovered to date can be grouped in two major categories designated P and F (Pedersen & Carafoli, 1987). The latter are defined as those of the F,F₂ type and are localized in the bacterial inner membrane. All of these enzymes that have been studied extensively, are hetero-oligomeric. Ion-motive ATPases of the P class are defined as those which form a covalent phosphorylated intermediate as part of their reaction cycle (Pedersen & Carafoli, 1987). Such ATPases, which are generally homo-oligomeric, are all inhibited by vanadate (Macara, 1980). All Mollicutes tested so far possess a membrane-bound ATPase activity (Razin, 1978) which is thought to play a central role in the cell volume regulation of these wall-less prokaryotes (Linker & Wilson, 1985a; Shirvan et al., 1987). Among them, mycoplasmas and acholeplasmas (Zilberstein et al., 1986; Rottem et al., 1987) all possess at least one membrane ATPase closely related to the eubacterial F,F₂ ATPases. In *Mycoplasma gallisepticum*, the presence of a second membrane ATPase transporting Na⁺ at alkaline pHs has been postulated (Shirvan et al., 1987), and a Na⁺-stimulated ATPase has also been described in *Acholeplasma laidlawii* (Lewis & McElhaney, 1983). The fact that (i) vanadate inhibits the *M. gallisepticum* enzyme (Linker & Wilson, 1985b), and (ii) the Na⁺-stimulated ATPase in *A. laidlawii* forms a covalent phosphorylated intermediate (Walderhaug et al., 1985), suggests that these two ATPases might be of the P type. In contrast, although a protein cross-reacting with the β subunit of *Escherichia coli* F,F₁-ATPase has been detected in *S. citri* and *Spiroplasma* sp. strain BNR1 (Rottem et al., 1987), very little is known about Spiroplasma ATPases. It was therefore of interest to determine if these organisms also possess both types of ATPase. To this end we have examined the effects of pH, in the presence or absence of vanadate, on the activity of solubilized *S. citri* ATPases. The results demonstrate that *S. citri* possesses two ATPases which differ markedly in their pH dependence and inhibitor sensitivity. These two activities were separated by chromatofocusing, and characterized by one- and two-dimensional gel electrophoresis. Heterologous hybridizations with selected probes were carried out to confirm the hypothesis that *S. citri* cells contain two types of ATPase.
Methods

Solubilization and partial purification of the membrane-bound ATPase activities. Membranes (3 mg protein ml⁻¹), isolated as previously described (Simoneau & LabarGre, 1988), were solubilized for 1 h at 40°C in solubilization buffer [40 mM-Tris/HCl pH 7.5, 1 mM-dithiothreitol, 25% (v/v) glycerol] supplemented with 1% (w/v) Triton X-100 (TX-100). Non-solubilized material was removed by centrifugation for 30 min at 4°C in a Kontron TST 55-5 rotor at 31,000 r.p.m. The supernatant was concentrated at 4°C by passage through a Minicon B15 cell (Amicon). This concentrate was then dialysed at 4°C against solubilization buffer containing 0.25% TX-100 until the assayable concentration of detergent in the sample was 2.5 mg ml⁻¹. One-tenth volume of 0.25 M-ethanolamine/acetate pH 9.4 was added to the sample just before loading onto a column (0.5 × 5.5 cm) of PBE94 (Pharmacia) which had been pre-equilibrated to pH 9.4 with 0.025 M-ethanolamine/acetate pH 9.4 containing 0.25% TX-100. Elution was at 4°C at a rate of 3 ml h⁻¹ with polybuffer 96 (diluted 1:10, Pharmacia) previously adjusted to pH 6 with acetic acid. One volume of 2× solubilization buffer containing 0.25% TX-100 was added to each collected fraction in order to minimize loss of ATPase activity during storage.

Assay of ATPase activity. ATPase activity was determined spectrophotometrically at 32°C by inorganic phosphate release as described by Dulley (1975) and expressed as nmol phosphate (mg protein)⁻¹ min⁻¹. The reaction medium contained, in a final volume of 100 µl: 5 mM-ATP, 50 mM-Tris/malate pH 6.5 or 8.5, 1.5 mM MgCl₂, 1.2 mM NaCl and either 10 µl of solubilized membranes (approximately 15–20 µg protein) or 40 µl of chromatofocusing fractions.

Electrophoresis of active enzyme. The solubilized enzyme was analysed by non-denaturing PAGE with ultrathin isoelectrofocusing 7.5–5% (w/v) acrylamide gels containing 0.1% TX-100. The location of ATPase was determined by staining the gels for activity according to Nimmo & Nimmo (1982). Briefly, gels were first soaked in equilibration buffer (50 mM-Tris/HCl, pH 8) for 30 min at 4°C, then in the same buffer containing 1.25 mM-MgCl₂, 5 mM-NaCl, 5 mM-ATP, 10 mM-CaCl₂, and incubated at 32°C for several hours until the precipitated calcium salt, formed upon release of inorganic phosphate, gave a clearly visible white band. The pH gradient generated during the electrophoresis was checked by comigrating pl-marker proteins (Mixture 9, Serva).

Electrophoresis in SDS-polyacrylamide gels. Isoelectric focusing (IEF) was performed according to O’Farrell (1975); for non-equilibrium pH gel electrophoresis (NEPHGE), TX-100 extracts were adjusted to 0.1% (w/v) SDS, 9.2 M-urea and 4% (v/v) ampholines (pH 3.5–10; LKB-Pharmacia). One volume of 9.2 M-urea, 2.5% (v/v) ampholines, 4% (w/v) Nonidet F40, 5% (v/v) β-mercaptoethanol was added to the samples just before loading the gels. Electrophoresis was then performed at 400 V for 4 h. SDS-PAGE in the second dimension was as described by Mouchè et al. (1979). For immunodetection, proteins were blotted onto nitrocellulose sheets using a semi-dry blotting system (Kyshe-Andersen, 1984).

Hybridization on nitrocellulose filters. DNA was cleaved with restriction enzymes, separated by electrophoresis on 0.8 agarose gels and transferred to nitrocellulose filters according to Southern (1975). Restriction fragments used as probes were purified from 1% (w/v) low-melting agarose (Seaplaque, FMC) gels, labelled with [³²P]dCTP by random priming (Feinberg & Vogelstein, 1984) and hybridized to genomic blots as described by Rasmussen & Christiansen (1987).

Analytical methods. Protein concentration was determined by the method of Bradford (1976) by including 0.1% TX-100 in the standards. TX-100 was determined by the method of Garenwal (1973).

Results

Characterization of two ATPases with different pH optima and sensitivities to vanadate in the membrane of S. citri

The ATPase activity of TX-100-solubilized membranes of S. citri was measured by determining the rate of release of P, from ATP at pH 4.5-9.5. The activity exhibited a pH optimum in the neutral range, with a maximum at about 6.5, and another in the mild-alkaline range (at about 8.5). At pH 4.5 or 9.5, the hydrolytic activity was nearly completely abolished, decreasing to less than 15% of maximal; however, full activity could generally be recovered when the pH was brought back to either of the optima (data not shown). The stability of enzyme to high pHs was essential for chromatofocusing experiments, which involve exposure of the enzyme to pH 9.4. Based on these results, the presence of two ATPases in the TX-100 extract of S. citri membranes was postulated.

One of the properties common to ion-motive ATPases involving a phosphorylated intermediate is inhibition by micromolar concentrations of orthovanadate (Hugentobler & Solioz, 1983; O’Neal et al., 1979). In prokaryotes, this inhibitor also distinguishes those ATPases from the proton-translocating ones, which are unaffected by low concentrations of vanadate. Fig. 1 shows the vanadate inhibition curves for the TX-100-soluble membrane ATPases at pH 6.5 and 8.5. Under our assay conditions, vanadate inhibited the S. citri ATPase only at the alkaline pH; half-maximal inhibition occurred at 5–7.5 µM-orthovanadate. At inhibitor concentrations of 40 µM or more, approximately 60% of the

Fig. 3. Elution profile of ATPase activity from a chromatofocusing column. TX-100 extracts were applied to a PBE94 column equilibrated at pH 9.4. Elution was performed with polybuffer 96 at a flow rate of 3 ml h⁻¹ and followed by measuring the absorbance at 280 nm (---). Fractions of 0.5 ml were collected and assayed for pH (---) and for vanadate-sensitive (○) and vanadate-insensitive (●) ATPase activity. The arrow denotes the addition of 1 m-NaCl.

activity remained vanadate insensitive. Therefore it appears that vanadate represents a tool to distinguish the two ATPases of S. citri: the activity measured at pH 6-5 mainly represents the vanadate-insensitive ATPase, whereas that determined at pH 8-5 in part corresponds to the vanadate-sensitive ATPase.

Isoelectric point of the vanadate-sensitive ATPase

The isoelectric point of the vanadate-sensitive ATPase was determined by running the TX-100 extract on non-denaturing polyacrylamide gels containing ampholines pH 7–9 (a, b) or ampholines 3–10 (c). Gels were stained for ATPase activity as described in Methods in the presence (b) or absence (a, c) of 50 μM-vanadate. Lanes 1 were loaded with 25 μg of proteins previously heated at 100 °C for 2 min. Lanes 2 and 3 contained, respectively, 12.5 and 25 μg of non-denatured protein. Numbers on the left and right refer to pH values determined as described in Methods.

Fig. 2. Electrophoresis of TX-100-solubilized proteins on native polyacrylamide isoelectric focusing gels. TX-100-released proteins were separated on 7.5% polyacrylamide gels containing either ampholines 7–9 (a, b) or ampholines 3–10 (c). Gels were stained for ATPase activity as described in Methods in the presence (b) or absence (a, c) of 50 μM-vanadate. Lanes 1 were loaded with 25 μg of proteins previously heated at 100 °C for 2 min. Lanes 2 and 3 contained, respectively, 12.5 and 25 μg of non-denatured protein. Numbers on the left and right refer to pH values determined as described in Methods.

Partial purification of the vanadate-sensitive ATPase

As described above, preliminary studies on the vanadate-sensitive ATPase showed that this enzyme has a fairly alkaline isoelectric point. Since most membrane proteins of S. citri are moderately acid rather than basic (Simoneau & Labarère, 1988), chromatofocusing seemed likely to be a powerful first purification step to enrich for the vanadate-sensitive ATPase from TX-100-solubilized membrane extracts. Fig. 3 shows the elution profile for chromatofocusing purification of S. citri vanadate-sensitive ATPase using PBE94. Elution with polybuffer 96 over a pH gradient of 9–6 resulted in a single peak of vanadate-sensitive ATPase activity at pH 8.62. Elution over the whole pH gradient did not result in elution of the second ATPase. However, this enzyme could subsequently be eluted with 1 M-NaCl. This second peak of ATPase activity corresponds to the vanadate-insensitive ATPase. The specific activity of the enzyme in the fraction eluted at pH 8.62 was 580 nmol mg⁻¹ min⁻¹ while that of the crude membranes was 40 nmol mg⁻¹ min⁻¹. The combination of the TX-100 extraction and chromatofocusing step resulted in a 14.5-fold purification of the vanadate-sensitive ATPase.

Analysis of the vanadate-sensitive ATPase components by one-dimensional electrophoresis

Fig. 4. Electrophoretic analysis of proteins from fractions eluted from the chromatofocusing column. Proteins were separated by SDS-PAGE and either stained by Coomassie blue (a) or blotted to nitrocellulose filters (b). Filters were used for immunodetection with anti-actin (lane 6) or anti-$\alpha$ subunits from yeast F, ATPase (lane 7) sera. Gels were loaded with either 60 $\mu$g of proteins from unfractionated TX-100 extracts (lane 1) or 50 $\mu$l of the following chromatofocusing fractions: fraction 6 (lane 2), 7 (lanes 3 and 6), 8 (lane 4) and 38 (lanes 5 and 7).

Fig. 5. Two-dimensional gel electrophoresis of the partially purified vanadate-sensitive ATPase. Proteins from the TX-100 extract (a, d) or the chromatofocusing fraction which eluted at pH 8.62 (b, c) were separated by IEF (a, b) or NEPHGE (c, d), followed by SDS-PAGE. Gels were stained with Coomassie blue. The arrows denote the 55 kDa polypeptide (D55), and the arrowheads the 37 kDa polypeptide (A37).

ATPase $\alpha$/$\beta$ subunits, two cross-reacting polypeptides of 50 and 52 kDa were detected (Fig. 4b, lane 7). This suggests that an ATPase serologically related to Fo,F, ATPases was present in the fractions which eluted with high saline concentrations.

Location by two-dimensional electrophoresis of the vanadate-sensitive ATPase on the protein map of $S$. citri

In order to identify the subunit(s) of the vanadate-sensitive ATPase among $S$. citri proteins, two-dimensional gels of either TX-100 extracts or chromatofocusing fractions eluted at pH 8.62 were compared (Fig. 5). When separated by IEF/SDS-PAGE, the latter was resolved into two major polypeptides (Fig. 5b). One polypeptide, with an apparent molecular mass of 55 kDa and an isoelectric point of approximately 6.0, corresponded to spot D55 in the TX-100 extract (Fig. 5a) (arrows). Previously published results have shown that this polypeptide is serologically related to actin (Simoneau & Lababere, 1990). The other polypeptide, with an apparent molecular mass of 37 kDa and a basic isoelectric point (higher than 7.5), corresponded to spot A37 in the TX-100 extract (arrowheads in Fig. 5). It has already been shown that this protein is located in membranes (Simoneau & Lababere, 1988). A faint spot

(FIG. 4a). Staining with Coomassie blue revealed one major polypeptide of about 37 kDa in the fraction corresponding to the peak of vanadate-sensitive ATPase activity (Fig. 4a, lane 3). Since this was the major component that noticeably increased in parallel with the increase of vanadate-sensitive ATPase activity, we concluded that the 37 kDa component was a subunit of this ATPase. There were minor contaminants with apparent molecular masses of about 55 kDa and 35 kDa. However, these two polypeptides both became more prominent in fractions which did not correlate with the ATPase activity (Fig. 4a, lanes 1 and 4). Since the 55 kDa contaminant did not separate from the 37 kDa polypeptide even when further chromatography on Sephadex G200 column was performed (data not shown) it was of interest to further characterize this component. Two 55 kDa proteins have been described in $S$. citri: the fibrillar protein (Townsend & Archer, 1983) and a protein serologically related to actin (Simoneau & Lababere, 1990). Blots of protein contained in the fraction eluted at pH 8.62 were reacted either with anti-fibrillar or anti-actin sera. Cross-reactivity was obtained only in the latter case (Fig. 4a, lane 6) leading us to conclude that the 55 kDa contaminant corresponded to the actin-related protein of $S$. citri. Electrophoretic analysis of proteins from the second peak of activity revealed about 20 separate polypeptides (Fig. 4a, lane 5), with subunit apparent molecular masses ranging from 10 to 80 kDa. When blots of proteins from this fraction were challenged with rabbit antiserum raised against yeast
other micro-organisms was checked. Genomic blots of S. citri DNA cleaved with EcoRI or HindIII were probed with either a 3.5 kb XbaI fragment from plasmid pMYC405 carrying the gene for the α subunit of Mycoplasma PG50 H+-ATPase (Rasmussen & Christiansen, 1987) or a 4-9 kb EcoRI fragment from plasmid pWE1001 carrying the kdp operon of E. coli, which encodes a P-type ATPase (Hesse et al., 1984). After a maximum of 24 h exposure, hybridization signals were visible in all lanes where S. citri genomic DNA was analysed (Fig. 6b, d). When the inserts from pMYC405 and pWE1001, respectively, were used as probes, the following fragments were reproducibly labelled: EcoRI 13.3 and 8.3 kb, HindIII 4.3 kb; and EcoRI 9.2 and 6.4 kb, HindIII 9.5, 4, and 2.6 kb. To ensure that the hybridization signals, obtained in such low-stringency conditions, were due to the inserts and not to the vector part of recombinant plasmids, controls were carried out by hybridizing the H+-ATPase probe with XbaI digests of pMYC405 (Fig. 6a). No hybridization signal corresponding in size to the vector pSP65 was obtained. The two signals obtained were for the linearized form of pMYC405 generated by partial hydrolysis and for the cloned insert, respectively. Hybridization of the kdp operon probe with EcoRI digests of pWE1001 (Fig. 6c) revealed two DNA fragments: one major band (4.9 kb) for the cloned insert and a weak signal (4.3 kb) for plasmid pBR322. In spite of this observation the hybridization signals obtained with S. citri DNA are likely to be due to the insert since probing citri genomic blots with pBR322 alone did not result in any hybridization signal, even under low-stringency conditions and after long times of exposure (data not shown).

Discussion

The data presented here support the notion that S. citri possesses at least two membrane-bound ATPases. In mycoplasmas, evidence has been presented that an ATPase, closely related to the F_{0}F_{1}-ATPase of E. coli (Zilberstein et al., 1986; Rasmussen & Christiansen, 1987) translocates protons across the membrane (Shirvan et al., 1987; Linker & Wilson, 1985b). Our results strongly suggest that an ATPase of the F-type is also present in spiroplasmas. Indeed, two proteins that specifically interact with antiserum against the α and β subunits of yeast F_{0}F_{1}-ATPase were detected in S. citri. Moreover, genomic DNA sequences of S. citri strongly hybridize with the Mycoplasma PG50 H+-ATPase operon, a sequence that shares regions of strong homology with the E. coli unc operon (Rasmussen & Christiansen, 1987). Based on structural relatedness, we

assume that this ATPase functions as an electrogenic H+ pump. In *S. citri* cells this enzyme constitutes only a part of the total ATPase activity. This conclusion rests on three lines of evidence: (i) the pH profile of the TX-100-solubilized activities shows two distinct peaks of maximal activity; (ii) two types of chromatographically separable activities differ in their vanadate sensitivity; (iii) sequences related to the *E. coli* kdp-operon which encodes a P-type ATPase exist in the *S. citri* genome. This latter observation and the observed vanadate sensitivity give ground to the speculation that this second ATPase may be of the P-type. This would support the idea that transport ATPases of this class are present in many, probably most, bacteria (Walderhaug *et al.*, 1989).

The recent finding that a protein of *Mycoplasma gallisepticum* cross-reacts with anti-yeast plasma membrane ATPase serum (Shirvan *et al.*, 1989), is also consistent with this assessment. However, the formation of a phosphorylated intermediate by the vanadate-sensitive enzyme of *S. citri* remains to be examined. If this intermediate is formed, this ATPase would be strikingly different structurally from other ATPases belonging to this class: the previously described enzymes all consist of a single peptide (a) of 70–100 kDa. Exceptions are the eukaryotic Na+-K+ ATPase, which contains an additional β peptide of approximately 55 kDa, and the Na+-stimulated ATPase of *Acholeplasma laidlawii*, which contains five subunits of 68, 55, 35, 27 and 16 kDa (Lewis & McElhaney, 1983). In the chromatographic fractions containing the partially purified vanadate-sensitive ATPase from *S. citri*, we found one major polypeptide of 37 kDa and two other polypeptides of 55 and 35 kDa. The latter is probably a contaminant since it could easily be separated from the enzyme preparation upon gel filtration. Several results also suggest that the 55 kDa component is not a subunit of the vanadate-sensitive ATPase: (i) the enrichment of this polypeptide during chromatofocusing does not completely correlate with the vanadate-sensitive activity; (ii) the location of this polypeptide, which cross-reacts with anti-actin antibodies and corresponds to spot D55 in the protein map of *S. citri*, is not restricted to the membrane (Simoneau & Labarère, 1988, 1990); and (iii) the isoelectric point of the native enzyme is nearly the same as that of the 37 kDa peptide, which may indicate that this enzyme is homo-oligomeric. On the other hand, the observation that the 55 kDa polypeptide does not separate from the 37 kDa component during gel filtration or during chromatofocusing raises the possibility of interactions between these two peptides in the native enzyme. Interestingly, it has been shown recently that a 55 kDa polypeptide of *S. citri* is reversibly phosphorylated *in vivo* (Rottem & Platt, 1989). However, more work is required before it can be concluded that this polypeptide corresponds to spot D55 or to any other 55 kDa protein spot (i.e. the fibrillar protein).

In view of the biological significance of ion-motive ATPases in the maintenance of constant internal pH and cell volume regulation, especially for Mollicutes, which lack a rigid cell wall, it would be interesting to determine the physiological function of the vanadate-sensitive ATPase of *S. citri*. Recent studies have shown that *M. gallisepticum*, may also possess two different ATPases (Shirvan *et al.*, 1987, 1989). Speculation that the Spiroplasma vanadate-sensitive enzyme is involved in sodium extrusion, as has been suggested in *M. gallisepticum*, is premature. Clearly, further research is needed to assign a role to the vanadate-sensitive ATPase. The successful separation of the two solubilized ATPase activities by chromatofocusing, reported here, will prove helpful for such future studies. As mentioned above, the vanadate-sensitive ATPase of *S. citri* might be structurally somewhat different from other P-type ATPases. Nevertheless, our hybridization data suggest that at least part of this enzyme resembles the *E. coli* kdp K+-ATPase, at the DNA level. This was unexpected if we consider the fact that in several Gram-positive bacteria no homologues of kdp genes were detected (Walderhaug *et al.*, 1989). However, phylogenetic studies have shown that Mollicutes arose by degenerative evolution from *Clostridium* spp. (Woese, 1987), and to our knowledge to date no clostridia have been tested. Heterologous hybridizations might also prove a useful tool for cloning and sequencing the gene for vanadate-sensitive ATPase. The small size of the vanadate-sensitive ATPase catalytic subunit of *S. citri*, compared to that of corresponding prokaryotic ATPases, may be in line with the concept of 'economy in genetic information' in micro-organisms with a small genome (Morowitz, 1984). Therefore such sequence data are of interest particularly from an evolutionary point of view and will probably provide information concerning the minimal features required in the mechanism of energized transport. Taken together, the results obtained by both the biochemical approach and the hybridization experiments will facilitate further functional and molecular characterization of Spiroplasma membrane ATPases, the ultimate objective of such studies being to obtain insights into the proton- and ion-pumping mechanisms in spiroplasmas. Our finding that two types of ATPase are present in the membrane of *S. citri* should greatly facilitate the interpretation of future results.

We would like to thank Dr Ole F. Rasmussen (Technical University of Denmark) for providing us with plasmid pMYC405 and Dr Wolfgang Epstein (University of Chicago, USA) for generous gift of plasmid PWE1001. The gifts of antibodies against the F1 subunits of yeast ATPase by Dr Michael G. Douglas (University of Texas, USA) and against the Spiroplasma fibrillar protein by Dr David L. Williamson (University of New York, USA) were very much
appreciated. We are indebted to Dr Martine GuCrin (CNRS, Bordeaux, France) for helpful discussions and to Dr Geraldine Fleming (University of North Carolina, USA) for assistance in the preparation of this manuscript. This work was supported by the Conseil Scientifique de l'Université de Bordeaux II and the Institut National de la Recherche Agronomique.
