(Received 15 February 1991; accepted 15 March 1991)

Introduction

The number of anaerobic fungi in the rumen is maximal in animals fed high-roughage diets, as in animals fed low-fibre rations the chytridiomycete population is reduced or absent (Bauchop, 1979). However, despite considerable interest in anaerobic fungi, information on their development in the rumen of animals receiving different diets is limited (Grenet et al., 1988). The contribution of the anaerobic mycoflora to feed digestion in the rumen has yet to be quantified.

The purpose of this work was to study morphological, physiological and biochemical properties of anaerobic fungi from the bovine rumen, and the isolation of chytridiomycetes from ruminants in the USSR is reported for the first time. The effect of different diets on the concentration of anaerobic fungal zoospores and the colonization of plant material in the bovine rumen was also investigated.

Methods

Animals and diets. The fungi were isolated from the rumen of 5-month-old rumen-fistulated calves fed a daily ratio of mixed cereal hay (3 kg) and concentrate (3 kg). The effects of different diets on the numbers of anaerobic fungi in the rumen were studied using four fistulated cows, each successively fed the following diets (kg d−1): (I) mixed cereal hay, 4.6; fodder beet, 24; corn silage, 20; energy concentrate, 8; (II) hay, 6; beet, 15; silage, 20; energy concentrate, 5; (III) hay, 8; beet, 10; silage, 20; energy concentrate, 5; (IV) wheat greens (harvested immediately before eating), 40; energy concentrate, 3. The rations were offered in two equal portions, at 8 am and 4 pm, for a 21 d period. Feeds were given separately, with 15 min intervals, in the following order: hay, silage, beet, concentrate. Refusals were collected after feeding and actual intakes were used for statistical analyses.

In period I (i.e. the time during which the animals received diet I), samples of rumen contents were taken 30 min before feeding and at 30 min intervals for 3 h after feeding. In periods II, III and IV the intervals between samples after feeding were 20 min. The rumen contents were filtered through two layers of gauze and mixed (1:1) with 2% (w/v) formaldehyde solution. Zoospores were counted in a Goryayev haemocytometer chamber; genera were established using the descriptions of Orpin (1975, 1976, 1977a).

The extent of fungal colonization of the substrate was determined by incubating timothy hay in nylon bags in the rumen. Leaves were cut into 15–20 mm fragments and placed into 50–170 μm porosity nylon bags (15 pieces per bag). The bags (8 × 7 cm in size) were tied to a 500 mm nylon cord and introduced through the fistula into the rumen just before feeding, and were incubated for 16 h. After incubation, the bags were removed and washed with tap water. Leaf fragments were placed onto glass slides, dried with filter paper and stained for 50 s with lactophenol blue. The procedure (Akin, 1987) was modified by using methylene blue instead of trypan blue. Colonization was determined on five leaf fragments from each animal. The number of sporangia was counted microscopically in five arbitrarily selected areas of a leaf fragment. Chitin substances were stained by the method of Ravindranath & Ravindranath (1975).

Isolation of anaerobic fungi. The primary isolation medium (Bauchop, 1979) contained (l−1): main solution, 900 ml; reducing agents, 10 ml; 5% (w/v) K2HPO4, 10 ml; and 5·6% (w/v) NaHCO3, 80 ml. The main
solution consisted of (NH₄)₂SO₄, 0.5 g; KH₂PO₄, 0.5 g; NaCl, 1.0 g; MgSO₄·7H₂O, 0.05 g; CaCl₂, 2H₂O, 0.05 g; peptone (Serva), 1.0 g; yeast extract (Difco), 1.0 g; 0.1% (w/v) resazurin, 1 ml; clarified rumen fluid, 170 ml; distilled water to 900 ml (Orpin, 1975). The reducing agents solution contained 2% (w/v) cysteine. HCl and 1% (Mountfort medium) or filter paper (8 x 40 mm strip) were added to the tubes before sterilization. The main solution was deoxygenated by boiling and 9 ml aliquots were dispensed anaerobically into culture tubes, which were sealed with butyl rubber stoppers (Belco Glass). All solutions were sterilized separately by autoclaving (121 °C, 30 min).

After sterilization, K₂HPO₄ (10 ml) and NaHCO₃ (80 ml) solutions were mixed anaerobically and 0.9 ml of the mixture and 0.1 ml of reducing agents solution were injected into each tube. Immediately before inoculation, 0.1 ml of a solution containing benzylpenicillin (sodium salt) and streptomycin sulphate was added into each test tube so that their concentrations in the medium were 1000 and 100 IU ml⁻¹, respectively. Pure cultures of the anaerobic fungi were isolated in this medium supplemented with 2% (w/v) agar and 0.2% (w/v) cellobiose, using the method of Joblin (1979). Purity of the cultures was checked microscopically after inoculation into a liquid medium containing glucose without antibiotics (Lowe et al., 1985). The isolates were subcultured at intervals of 2-4 d with a 5% (v/v) inoculum.

The fungi were also cultured on a semi-defined modification of the above medium in which the rumen fluid was replaced by solutions of volatile fatty acids (VFA, 10 ml), vitamins (10 ml), trace elements (10 ml), haemin (10 ml) and distilled water (130 ml). The VFA (Caldwell & Bryant, 1966) did not include methyl butyrate. The vitamin solution was prepared as described by Lowe et al. (1985) and modified to contain biotin (200 mg l⁻¹); nicacin was included instead of nicotinamide and naphthoquinone was not included. The trace element solution contained (mg per 100 ml): CaCl₂, 2H₂O, 140; FeSO₄·7H₂O, 10; MnSO₄·5H₂O, 220; ZnSO₄·7H₂O, 220; H₂BO₃, 10; Na₂MoO₄·2H₂O, 15; Na₂SeO₃, 1.5; Na₂SiO₃·6H₂O, 3.8; NH₄VO₃, 1.2; KI, 1.5; CuSO₄·5H₂O, 4; CoCl₂·6H₂O, 4; LiSO₄, 0.8; NiCl₂·6H₂O, 0.4; and AlCl₃·6H₂O, 0.9, as suggested for the cultivation of cellulolytic micromycetes (A. V. Shulga, unpublished data). The haemin (0.1% w/v) was dissolved in a 1:1 (v/v) mixture of ethanol and 0.05 M-NaOH. The trace element solution was added to the stock solution before sterilization. The haemin and VFA solutions were sterilized by autoclaving (121 °C, 30 min) and the vitamin solution was sterilizer-sterilized. After sterilization, solutions of haemin (10 ml), NaHCO₃ (80 ml) and K₂HPO₄ (10 ml) were mixed anaerobically and the combined solution (1 ml), vitamins (0.1 ml), VFA (0.1 ml) and reducing agents solution (0.1 ml) were injected into tubes of sterile medium.

**Results**

**Characterization of strains isolated**

Two principal morphological types of fungi that differed in thallus form and size as well as in number of flagella and zoospore morphology were present. Cultures of anaerobic fungi with multiflagellate zoospores and with uniflagellate zoospores were isolated. One representative strain of each type, that grew well under the cultivation conditions used, was selected for detailed study.

**Morphology and life cycle of strain NC71**

The vegetative body was a branched septum-free colourless rhizoid that penetrated deeply into the plant tissue and reached 400 μm in length and 10–15 μm in thickness at the base. The thallus was monocentric. The sporangium formed on the surface of the substrate and was usually of ovoid or spherical form, 70–90 μm in diameter. The colonies that formed in the agar medium in roll tubes were round and hyaline, up to 2 mm in diameter, with irregular edges. A cluster of up to 250 sporangia with radial mycelial hyphae was visible in the centre of the colony. The zoospores, 15–20 x 10–12μm in size, were oval, and possessed from 2 to 12 (7 ± 2, n = 40) flagella that were up to 40 μm in length. Living zoospores were refractile.

Attachment to the inner walls of the culture tubes usually occurred in 1–2 h. The attached zoospore encysted and germinated; the flagella were usually, but not always, rejected. After 2–2.5 h the rhizoid was 40–50 μm in length. The main rhizoid then began to branch and grew rapidly up to a maximum rate of 30 μm h⁻¹ by 15 h after inoculation. The sporangium growth rate during this period reached 24.8 μm h⁻¹. Subsequently, the size of the rhizoid increased, mainly by the growth of side hyphae. The rhizoid ceased to grow by 18–20 h after inoculation. At this stage a partition was formed between
Table 1. Principal end-products of substrate fermentation by strains NC71 and PC12
Composition of the fermentation end-products was determined after 4-6 d growth in the semi-defined medium with wheat straw, filter paper and cellobiose. The results are means ± standard error (n = 4). Gaseous end-products were not determined.

Morphology and life cycle of strain PC12
The rhizoid was septum-free and hyaline. The length of the main rhizoid ranged from 200 to 250 μm and its thickness at the base was 6-8 μm. The thallus was monocentric, of the intramatrix type. The sporangium (up to 90 μm in length) was cylindrical. Colonies in the agar medium in roll tubes were hyaline, 1-1.5 μm in diameter, with irregular edges. The zoospores were oval and 10-12 × 5-7 μm in size. A single flagellum, 25-30 μm in length, was usually present. Non-motile cells with two to five flagella sometimes occurred, probably due to disturbances in zoosporogenesis. When the zoospores ceased to move they became spherical. Within 1-2 h of inoculation the zoospores attached to the substrate, encysted and germinated. After attachment for 10 h the sporangium was 55-60 μm in length; the thickness had increased insignificantly from 5 to 8 μm. After 18-20 h, the thickness of the sporangium had reached 28-30 μm, a septum had formed between it and the rhizoid, and the internal differentiation of the zoospores had become noticeable. Liberation of the zoospores occurred 21-24 h after the release of the parent zoospore.

Physiological and biochemical properties of the isolated strains
Growth of strains NC72 and PC12 was observed at 33-42 °C, and pH 6.0-7.0, with optima at 39 °C and pH 6.5-6.7 respectively. Both strains were strictly anaerobic and unable to grow in liquid medium in the presence of air. Both fungi grew well in liquid semi-defined media with wheat straw, timothy hay, filter paper, Avicel, soluble starch, xylan, D-glucose, D-xylose, D-lactose, D-maltose, D-sucrose or D-cellobiose as sole substrates. Fructose and melibiose were utilized poorly by NC71 and PC12 respectively. Growth of the strains was poor with CMC and pectin in both liquid and agar media in roll tubes. Polygalacturonic acid, aesculin, L-arabinose, D-galactose, lyxose, D-mannose, L-rhamnose, D-ribose, L-fucose, erythrose, dulcitol, i-inositol, D-mannitol, D-raffinose and D-trehalose were not assimilated.

The principal fermentation end-products of wheat straw, filter paper and cellobiose produced by strains NC71 and PC12 are presented in Table 1. Gaseous end-products were not determined.

In the liquid semi-defined medium with wheat straw, strains NC71 and PC12 synthesized CMCase, Avicelase, cellobiase, amylase and xylanase. Extracellular activities of the enzymes in the culture supernatant after 3 d growth are given in Table 2. Temperature and pH optima for CMCase, cellobiase and xylanase were 50 °C and 6-0, 50 °C and 5-5, 45 °C and 6-0, respectively.
Fig. 1. Numbers of zoospores of (a) Neocallimastix and (b) Piromyces and Sphaeromonas (Caecomyces) in the initial 3 h of the postfeed period in cows fed one of four different rations: ■, I; ▲, II; ●, III; ▼, IV. Zoospore concentrations were determined in samples of rumen contents taken 30 min before feeding (zero point on the abscissa) and then at intervals of 30 min (period I) or 20 min (periods II, III and IV) for 3 h into the postprandial period.

Effect of diet on the anaerobic fungal population in the rumen

Uni- and multilagellate zoospores of anaerobic fungi were found in the rumens of test animals fed all diets. The multilagellate spores had an oval or round monad with granular cytoplasm and 2-15 flagella. The cell size varied from 12-20 μm. The number of multilagellate zoospores observed in rumen fluid on diets I, II, III and IV was 7 x 10^3 – 5 x 10^4 ml^-1. Two types of unilagellate zoospores were detected, i.e. large round or oval (10-15 μm in diameter) and small round (3-8 μm). The ruminal population of these zoospores on diets I, II, III and IV was 10^4-10^5 ml^-1. The multilagellates were identified using morphological features, size and character of locomotion as reproductive cells of the fungus Neocallimastix sp. The unilagellates were designated as zoospores of Sphaeromonas (syn. Caecomyces) and Piromyces spp. using the same criteria.

Before feeding, the concentration of all morphological types of zoospores was relatively low. After feeding, zoospore numbers increased significantly and were maximal after 90 min in period I and between 40 and 60 min in periods II, III and IV. By 3 h after feeding, zoospore numbers in the rumen fluid had fallen to the initial level (Fig. 1a, b). The number of zoospores was highest in the animals receiving the fibre-enriched diet III and was lowest in those fed pasture grass (diet IV).

Chitin-containing cylindrical, oval and fusiform bodies, identified as anaerobic fungal sporangia, were detected microscopically on the leaf surfaces after incubation in the rumen. Oval sporangia, 30-60 μm in length, predominated. The cylindrical sporangia reached 60-90 μm in length. The fusiform sporangia were the smallest (< 30 μm), and probably represented immature forms of the other zoosporangia types. The sporangium surface was rough. Some preparations had distinct smooth hyaline rhizoids up to 10 μm thick that originated from the base of the sporangium. Fungal thalli were mostly attached to leaf veins. The extent of colonization varied with diet and correlated positively with the proportion of hay in the ration (r = 0.82, P < 0.01) and negatively with the quantity of beet (r = -0.67, P < 0.05). When the animals were fed the maximal amount of hay and the minimal amount of beet (in diet III), the number of sporangia on the leaf surface reached 1.7 x 10^5 cm^-2, which was 2.5 times as high as with diet I (Table 3).

Discussion

The strains isolated differed in thallus and zoospore morphology, the composition and ratio of fermentation end-products and the level of extracellular enzyme activities. Using these features, strains NC71 and PC12 were assigned to the Chytridiomycete genera Neocallimastix and Piromyces, respectively. Neocallimastix sp. NC71 had similar zoospore morphology to N. frontalis (Heath et al., 1983) and N. patricia (Orpin & Munn, 1986) but differed from these Neocallimastix spp. in the

proportion of the main fermentation end-products formed from various substrates (Phillips & Gordon, 1988; Breton et al., 1989).

Strain PC12 was similar to *Piromyces communis* (Orpin, 1977a) but differed as it could use both sucrose and melibiose for growth, and was unable to utilize raffinose. This is the first description of a strain of *Piromyces* that is able to grow on melibiose (Phillips & Gordon, 1988). Strain PC12 also differed from other strains of *Piromyces* sp. that have been isolated (Fonty et al., 1988) in its zoospore morphology and in the nature and ratio of the main fermentation end-products. The paucity of detailed information on the physiological and biochemical properties of *Piromyces* sp. precluded the assignment of strain PC12 to a definitive species.

The marked increase in the concentration of zoospores of anaerobic fungi from the genera *Neocallimastix*, *Sphaeromonas* (*Caecomyces*) and *Piromyces* in rumen fluid in the first hour after feeding has been reported previously and highlights the dependence of the induction of zoosporogenesis on feed intake (Orpin, 1977b; Bauchop, 1979). The delayed release of zoospores in animals receiving diet I (high in concentrates) may have been due to this low-raghage ration being deficient in plant-associated inducers of zoosporogenesis (Orpin, 1977b).

In our experiments the concentration of zoospores in the rumen fluid and extent of colonization of timothy leaves were maximal when the animals were fed the high-raghage diet (III) and were minimal when they were fed diet IV. Although the experiments continued over a 12-week period and seasonal variations in the populations may have occurred, the observed differences are more likely to be due to diet effects, as reported by Bauchop (1979, 1981) and Grenet et al. (1988). In period II, with an increased proportion of hay and decreased concentrate and beet in the diet, a fall in the zoospore numbers and the extent of colonization of timothy leaves was observed in two of the four animals under study. However, the correlation analysis confirmed the dependence of the extent of colonization in the rumen on the proportion of hay and beet in the diet.

As zoospore concentration in filtered rumen fluid is not a reliable marker of the biomass and metabolic activity of anaerobic fungi in the rumen (Bauchop, 1979), a better estimate may be obtained by determining the extent of fungal colonization of the substrate in nylon bags *in situ*.
