(Received 4 May 1993; revised 17 June 1993; accepted 20 July 1993)

When cultured on a mixture of cellobiose and cellulose, *Clostridium* C401 did not initially attach to cellulose but remained in the liquid phase. After cellobiose exhaustion, bacterial cells grew in association with the insoluble cellulose. Carboxymethylcellulase (CMCase) production on Avicel cellulose was four- to fivefold greater than on cellobiose, and cellulose-grown cells adhered to filter paper with an initial adhesion rate about four- to fivefold greater than did cellobiose-grown cells. Using tritiated thymidine incorporation as a measure of growth, it appeared that transfer of strain C401 from cellobiose to cellulose required an adaptation phase. An extracellular cellulase complex was isolated by affinity chromatography. This enzyme system is a multicomponent aggregate (molecular mass above 5 MDa), and yielded two major polypeptide bands by SDS-PAGE having molecular masses of 130 and 70 kDa. Cellobiose strongly inhibited Avicelase activity and slightly inhibited *p*-nitrophenylcellobiose hydrolysis (pNPCase), but had no effect on the CMCase activity of the cellulase complex. In addition, polyclonal antibodies, raised against the purified 130 kDa protein inhibited Avicelase activity, but not CMCase and pNPCase activities.

**Introduction**

The mesophilic, cellulolytic *Clostridium* C401 which was isolated with nine other strains from a municipal solid waste digester (Benoit et al., 1992), produces extracellular cellulases, and is able to degrade crystalline cellulose extensively. Previous experiments, using tritiated thymidine incorporation, demonstrated that growth of strain C401 on cellulose occurred only when bacteria were attached to the substrate (Gelhaye et al., 1992a). Adhesion of strain C401 to cellulose is a specific process which is regulated by the presence of cellobiose (Gelhaye et al., 1993a). Cellobiose, the major end-product of cellulolysis, is known to repress the synthesis of activity for crystalline cellulose hydrolysis (Avicelase) by the thermophilic *Clostridium thermocellum* (Johnson et al., 1985). Furthermore, the predominant forms of the bacterial cellulases detected in the culture supernatant were affected by the nature of the substrate (Saddler & Khan, 1981) and this has also been shown for strain C401 (Cailliez et al., 1993). However, the regulation of cellulase production in mesophilic, cellulolytic clostridia has not been extensively analysed and no study on the regulation of cellulose colonization has been published. The aim of the present work was to characterize some effects of cellobiose on cellulose colonization by *Clostridium* C401.

**Methods**

**Organism and culture conditions.** Strain C401 was grown anaerobically in the medium of Benoit et al. (1992) to which the desired carbon source was added as described below.

**Thymidine incorporation rate.** Batch cultures (9 ml) were grown as described previously (Gelhaye et al., 1993b) in N2-flushed Hungate tubes containing Avicel cellulose (0.75%, w/v) with or without cellobiose (0.2%, w/v). In the course of fermentation, filter-sterilized thymidine (Amersham) (labelled and unlabelled) was added so that the final concentration was 42 μM and 2.1 μCi ml⁻¹ (77 kBq ml⁻¹). At this concentration, the incorporation of added thymidine into DNA, defined as the cold trichloroacetic acid (TCA)-precipitable fraction, was not limiting (Gelhaye et al., 1992a). At the end of the time course (2 h), separation of attached and free cells was performed as described previously (Gelhaye et al., 1993b). The TCA extraction and radioactivity measurement were performed immediately using the method of Fuhrman & Azam (1982). Values obtained were converted to d.p.m. (ml culture)⁻¹.

**Biomass detection.** The determination of attached and free biomass was based on bacterial protein estimation as described by Bensaadoun & Weinstein (1976). The values obtained were converted to mg cells ml⁻¹. Calibrations were performed with cellobiose-grown cells to estimate the relationship between the optical density, dry weight and protein content of the cells.

**Reducing sugars.** The quantity of reducing sugars was determined by the method described by Miller (1959). In several cases, sugars in the
supernatant fluid were detected by HPLC (SP8430 Spectra-Physics) using a polypropylene H column.

Analytical methods. To detect ethanol and acetate, samples were centrifuged at 13 000 g for 15 min. A 1 ml sample of culture supernatant was acidified with 50 μl n-butanol in 6 M-HCl. A portion (2 μl) of the acidified supernatant was injected into an Intersmat IGC 121 FL gas chromatograph equipped with a flame ionization detector. Separation took place in a 2 m glass column packed with Porapack Q, 100/120 mesh. Nitrogen was used as the carrier gas. Injector and detector temperatures were 230 °C, and column temperature was 175 °C. The analysis of chromatographic data was done by an Intersmat IRC 1B integrator.

Lactate (D and L) was detected spectrophotometrically with the appropriate enzyme kit (Boehringer Mannheim).

Bacterial adhesion. In cellulose culture, bacteria were harvested in the exponential phase of growth by centrifugation and washed twice with 50 mM sodium phosphate buffer, pH 7.8. In Avicel cellulose culture (50 ml), cellulose and bacteria in exponential phase were harvested by centrifugation. The supernatant was discarded and the pellet was resuspended in sodium phosphate buffer, pH 7.8. Pelleted cells were suspended in sodium phosphate buffer, pH 7.8.

Measurements of adhesion to filter paper were performed as described previously (Gelhaye et al., 1992b).

Cellulase complex isolation. Strain C401 (500 ml) was grown on Avicel cellulose (0.1 %, w/v). Bacteria were pelleted by centrifugation in the late phase of growth (96 h). The supernatant fluid was concentrated by ultrafiltration using an Amicon PM10 membrane. This concentrate was applied to an Avicel cellulose-packed column (1.5 x 30 cm) equilibrated with 100 mM-Tris/HCl buffer (pH 7.8). The column was washed with the same buffer to elute the unattached fraction. The adhered fraction (cellulase) was eluted with deionized water (pH 6.4). In several cases, the cellulase fraction was concentrated by ultrafiltration and fractionated on a gel filtration column (Sepharose CL4B, 2.5 x 30 cm) equilibrated with 100 mM-Tris/HCl buffer (pH 7.8). In several cases, the cellulase fraction was concentrated by ultrafiltration and fractionated on a gel filtration column (Sepharose CL4B, 2.5 x 30 cm) equilibrated with 100 mM-Tris/HCl buffer (pH 7.8).

Enzyme activities. Endoglucanase activity (CMCase) was determined by incubating the enzyme preparation (100 μl) with carboxymethylcellulose (CMC) for 30 min and measuring reducing sugars as described by Miller et al. (1960). Each reaction mixture contained Tris/HCl buffer (pH 7, 0.075 mmol); CMC (20 mg), distilled water and enzyme preparation in a total volume of 2 ml.

Avicelase activity was determined by incubating the enzyme preparation (100 μl) with the following mixture (in a total volume of 5 ml): 0.15 mmol Tris/HCl buffer (pH 7); 1.33 mg Avicel; 50 μmol dithiothreitol; 25 μmol CaCl2 and distilled water as described by Cavedon et al. (1990). At the end of incubation (72 h), insoluble material was removed by centrifugation and the amount of reducing sugars was measured as described by Miller et al. (1960).

The p-nitrophenylcellobiosidase (pNPCbase) was measured by incubating the enzyme preparation (100 μl) with p-nitrophenyl-cellobioside for 1 h as described previously (Cuilliez et al., 1993). Each reaction mixture contained Tris/HCl buffer (pH 7, 0.03 mmol), p-nitrophenylcellobioside (1-0 mg), distilled water and enzyme preparation (100 μl) in a total volume of 1 ml.

To measure the effects of cellulose on the three activities, cellulose at different concentrations was added to these reaction mixtures.

SDS-PAGE and zymogram. Polypeptides were separated by SDS-PAGE. Electrophoresis in polyacrylamide slab gels (stacking gel, 5% w/v, acrylamide; running gel, 12% acrylamide) was performed in Tris (25 mM)/glycine (192 mM) buffer (pH 8.3) in the presence of SDS (0.1% w/v) with the gel system of Laemmli (1970).

CMCase zymograms were prepared by using 0.1% CMC copolymerized with 7-5% polyacrylamide as described by Shoseyov & Doi (1990), without first removing SDS. CMCase activities were visualized with Congo red after a 15 h incubation at 37 °C. Washing gels to remove SDS did not alter the banding pattern on the zymograms.

P1 antiserum production. Isolated cellulase (1 mg) was resolved by preparative SDS-PAGE. The gel was stained with Coomassie blue and the 130 kDa (P1) band was cut out and used as an immunogen. P1 preparation (100 μg) was mixed with Freund's complete adjuvant and injected into New Zealand White rabbits. The second and third injections were done after 2 week and 1 month intervals using the same quantity of protein. A final injection of 100 μg was done 2 months after the third injection and the serum was collected 10 d later. Western blot analysis was performed to confirm specific interaction between antiserum and P1 at 1:500 dilution.

CMCase, pNPCbase and Avicelase were tested in the presence and absence of antiserum. A preparation of cellulase complex (100 μl, 2 mg ml⁻¹) was mixed with different volumes of antiserum (0.5, 1 or 2 μl). After this pre-incubation step (30 min), CMCase, pNPCbase and Avicelase activities were tested as described above.

Results and Discussion

Effects of cellulose on cellulose colonization

Previous studies have shown that growth of strain C401 on Avicel cellulose occurs when bacteria are attached to their substrate (Gelhaye et al., 1992a). The presence of cellulose strongly modified the colonization of Avicel cellulose by strain C401 (Fig. 1). The fermentation can be divided into four stages.

In the first stage (0–15 h), growth occurred in the liquid phase containing cellulose without bacterial attachment to cellulose (Fig. 1a–c). The doubling time (4 h) of the free population corresponded to growth on cellulose alone (Benoit et al., 1992).

In the second phase (15–25 h), bacteria were found attached to the cellulose (Fig. 1a, b). About 60% of the biomass found free in the first stage, was attached to the cellulose after 25 h. The growth rate of the attached population (doubling time about 6 h) was slightly greater than that on cellulose alone (8 h; Gelhaye et al., 1992a), suggesting that growth occurred on the cellulose still present in the culture (Fig. 1c).

Between 25 and 50 h, the thymidine incorporation rate decreased within the attached biomass without increase in the free population (Fig. 1b). This decreased growth was correlated with a cessation of metabolite production (Fig. 1d) and exhaustion of the cellulose (Fig. 1c). Apparently, adaptation to cellulose degradation occurred.

In the last stage (after 50 h), an increase of the thymidine incorporation rate was observed in both attached and free cells (Fig. 1b). The slight increase of the free biomass did not explain the observed burst.
Regulation of cellulose colonization by *Clostridium C401*

Fig. 1. Effects of cellobiose (0.2%) on cellulose (0.75%) colonization by strain C401. (a) Formation of attached (●) and free (○) biomass; (b) thymidine incorporation into attached (●) and free (○) cells; (c) reducing sugar concentration; (d) acetate (■), ethanol (○) and lactate (●) production. Each point is the mean ± SD of four determinations from two separate cultures.

Analysis by HPLC of the supernatant did not reveal sugar concentrations above 0.05 g l⁻¹ (data not shown). At the same time, a slight decrease in the amount of acetate (Fig. 1d) was observed, suggesting that it was used after the exhaustion of cellobiose (Fig. 1c). These results could indicate that the free cells had exhausted their carbon source. The obligatory completion of initiated rounds of DNA replication and cell division could explain the changes in the rate of thymidine incorporation into free cells (Wanner & Egli, 1990; Gelhaye et al., 1993b). Furthermore, the consumption of acetate by bacteria depleted of their carbon source has been reported for several micro-organisms without additional biomass formation (Niven et al., 1977; Anderson & Von Meyenburg, 1980). At the same time, the growth of the attached population was low (doubling time about 15 h), suggesting that bacteria were in the decelerating phase, possibly due to an accumulation of end-products or to a fall of pH.

Effects of cellobiose on CMCase production

CMCase production was measured in Avicel cellulose (0.75%, w/v) and cellobiose (0.5%, w/v) cultures. In both cases, the total activity of CMCase paralleled growth. However, as shown in Fig. 2, the specific activity was about four- to fivefold greater during growth on Avicel cellulose [2 IU (mg cells⁻¹)] than on cellobiose [0.5 IU (mg cells⁻¹)]. In the presence of Avicel and cellobiose (0.5%, w/v), the lowered CMCase specific activity [0.5 IU (mg cells⁻¹)] confirmed that cellobiose regulates the production of CMCase by strain C401. Furthermore, this regulation could explain, at least in part, the adaptation phase to cellulose degradation observed in cellobiose-grown cells (Fig. 1).

Effects of cellobiose on strain C401 adhesion

Cellobiose-grown cells adhered to filter paper (Fig. 3), with an initial adhesion rate, calculated using the initial slope of the plot, of 7 × 10⁻⁴ mg cm⁻² min⁻¹. The rate was about four- to fivefold greater with cellulose-grown cells.
Fig. 3. Adhesion of cellulose- (○) and cellobiose- (□) grown cells to Whatman no. 1 filter paper. The total biomass was 0.25 mg dry wt ml⁻¹. Each point is the mean ± SD of four determinations from two separate experiments.

(32×10⁻⁴ mg cm⁻² min⁻¹). Thus, the production of adhesion factor(s) was limited in cellobiose-grown culture. It is interesting to note that the same sharp decline (four- to fivefold) occurred in both CMCase activity and adhesion factor(s), in cellobiose-grown cultures compared with cellulose-grown cultures. These results suggested that cellulase synthesis and adhesion were coregulated.

Previous studies demonstrated that adhesion of cellulose-grown cells was regulated by cellobiose (Gelhaye et al., 1993a). Effects of cellobiose were the same with cellobiose-grown cells. Bacterial adhesion was enhanced at cellobiose concentrations between 0.05 and 0.15% (w/v). Conversely, at higher concentrations, cellobiose inhibited adhesion of strain C401. These results could explain the changes in bacterial adhesion observed in the first stages (0–25 h) of the fermentation described above (Fig. 1).

These results suggested that cellobiose plays a major role in the regulation of cellulose colonization by strain C401, in particular concerning adhesion.

**Strain C401 cellulase complex**

The extracellular complex was isolated from the crude protein mixture by taking advantage of the extremely high affinity of the complex for cellulose. The cellulase complex could be washed from cellulose by deionized water. This eluted fraction contained 80% of the initial CMCase activity. When this fraction was applied on a Sepharose CL4B column, we observed a single major absorbance peak that eluted before thyroglobulin (669 kDa). Molecular mass standards larger than thyroglobulin were not available, but we have estimated by extrapolation that the aggregate has a molecular mass above 5 MDa. The cellulase complex was resolved by SDS-PAGE to reveal two major polypeptide bands having molecular masses of 130 kDa (P1) and 70 kDa (P2), and several minor polypeptides (Fig. 4, lane 3). Consequently, as with many cellulolytic clostridia (Lamed et al., 1987; Lamed & Bayer, 1988), the strain C401 cellulase was a multiprotein complex composed of different subunits having a heterogeneous stoichiometry.

A test for CMCase activity was performed on the proteins separated by SDS-PAGE (Fig. 5, lane 2). Several CMCase activities were detected but the major protein P1 had no detectable hydrolytic activity.
Regulation of cellulose colonization by Clostridium C401

Effect of P1 antiserum on cellulase activity

We tested the effect of the P1 antiserum on the cellulase complex to determine whether it could inhibit specific enzyme activities. The antiserum was mixed with the isolated cellulase complex (2 mg ml⁻¹) and this mixture was tested for Avicelase, CMCase, and pNPCbase activities (Fig. 6). Antiserum inhibited Avicelase activity but not CMCase and pNPCbase activities of the complex.

Consequently, as with many cellulolytic clostridia, strain C401 produces a cellulase complex which is able to degrade crystalline cellulose. Furthermore, the major protein of the complex (P1) showed characteristics similar to that of C. cellulovorans P170 (CbpA), i.e. high affinity for cellulose, no apparent hydrolytic activity, and its presence is necessary for Avicelase activity (Shoseyov & Doi, 1990).

Effects of cellulose on the strain C401 cellulase

Effects of cellulose were observed on the CMCase, pNPCbase and Avicelase activities of the strain C401 cellulase complex (Fig. 7). Cellulose strongly inhibited Avicelase activity, and inhibited pNPCbase activity to some extent, but did not inhibit CMCase activity. These results suggested that cellulose inhibited a factor which was not implicated in CMCase and pNPCbase activities, but which was necessary for the degradation of crystalline cellulose.

Strain C401 produces a cellulase complex which resembles that of C. cellulovorans (Shoseyov & Doi, 1990). This study demonstrated that cellulose has an important function in the regulation of cellulose colonization by strain C401 at several levels. Cellulose regulates (i) the production of CMCase activity, (ii) the production of bacterial adhesion factor(s), (iii) bacterial adhesion to cellulose, and (iv) the Avicelase activity of the cellulase complex. Furthermore, the shift of growth of strain C401 from cellulose to cellulose required an adaptation phase. Further investigations are required to characterize the factors implicated in these observed regulations.

This work was supported by a fellowship to E.G. from the Agence de l’Environnement et de la Maîtrise de l’Energie (ADEME) and from Gaz de France.
