(Received 2 February 1993; revised 19 May 1993; accepted 25 May 1993)

Multiple forms of \( \beta \)-glucosidase (EC 3.2.1.21) of Sporotrichum thermophile were produced when the fungus was grown in a cellulose medium. One \( \beta \)-glucosidase was purified 16-fold from 6-d-old culture filtrates by ion-exchange and gel-filtration chromatography. The purified enzyme was free of cellulase activity. It hydrolysed aryl \( \beta \)-D-glucosides and \( \beta \)-D-linked diglucosides. It was optimally active at pH 5.4, at 65°C. The apparent \( K_m \) values for \( p \)-nitrophenyl \( \beta \)-D-glucoside (PNPG) and cellobiose were 0.29 and 0.83 mM, respectively. Glucose, fucose, nojirimycin and gluconolactone inhibited \( \beta \)-glucosidase competitively. At high ( > 1 mM) substrate concentration, \( \beta \)-glucosidase catalysed a parallel transglycosylation reaction. The transglycosylation product formed from cellobiose appeared to be a \( \beta \)-linked tetramer of glucose. Admixtures of \( \beta \)-glucosidase and cellulase components showed that the concept of cellobiose inhibition of cellulases was not valid for all components of the cellulase system of S. thermophile. \( \beta \)-Glucosidase supplementation also stimulated cellulose hydrolysis by cellulases when there was no accumulation of cellobiose in reaction mixture.

Introduction

\( \beta \)-Glucosidase, which hydrolyses variously \( \beta \)-linked diglucosides and aryl-\( \beta \)-glucosides, has been studied from several microbial sources (Woodward & Wiseman, 1982). Interest in this enzyme centres on its role in enzymic hydrolysis of cellulose. The presence of \( \beta \)-glucosidase in cellulase preparations has been reported to stimulate the rate and extent of cellulose hydrolysis (Sternberg, 1976). This effect has been explained by the concept that it relieves the inhibition by cellulose-derived cellobiose of cellulase activity (Sternberg, 1976; Wood & McCrae, 1982). \( \beta \)-Glucosidase has therefore been regarded as a component of the cellulase system although it has no direct action on cellulose. Cellulolytic fungi have been found to release \( \beta \)-glucosidase into the culture broth when grown with cellulose as the carbon source (Deshpande et al., 1978; Kubicek, 1981; Lusis & Becker, 1973; McHale & Coughlan, 1982; Sadana et al., 1983; Shewale & Sadana, 1978; Smith & Gold, 1979; Wood & McCrae, 1982). Canevascini & Meyer (1979) reported an exception: the thermophilic fungus Sporotrichum thermophile did not produce \( \beta \)-glucosidase extracellularly. S. thermophile degrades cellulose faster than Trichoderma reesei, one of the most powerful mesophilic cellulolytic fungi (Bhat & Maheshwari, 1987). Therefore, the biochemical characterization of the cellulase system of S. thermophile is of interest. We have purified and characterized an extracellular \( \beta \)-glucosidase from S. thermophile and studied its effect on cellulase activity of S. thermophile.

Methods

Organism. Strain IIS 220 of S. thermophile was used. Its isolation and characteristics have been described by Bhat & Maheshwari (1987). This strain was chosen because of its high extracellular \( \beta \)-glucosidase activity.

Enzyme assays. Endoglucanase (EC 3.2.1.4) activity was measured on sodium carboxymethylcellulose, exoglucanase (EC 3.2.1.91) activity was measured on microcrystalline cellulose, and \( \beta \)-glucosidase (EC 3.2.1.21) activity was measured using PNPG or cellobiose as described previously (Bhat & Maheshwari, 1987).

Production and purification of \( \beta \)-glucosidase. Step I. The fungus was grown in a cellulose/ammonium dihydrogen phosphate medium (Bhat & Maheshwari, 1987). On day 6, when \( \beta \)-glucosidase activity was maximal, the culture broth (5–7 litres) was filtered through glasswool to remove cellular material. The culture filtrate was processed for
isolation of β-glucosidase as described. All steps were done at room temperature, unless specifically mentioned otherwise.

Step II (ammonium sulphate precipitation). The pH of the light-brown culture filtrate was brought to 4.0 by the addition of glacial acetic acid. Ammonium sulphate powder was then added to 80% saturation with continuous stirring. The preparation was kept overnight at 4°C to allow precipitated protein to sediment. The clear solution at the top was siphoned off and discarded. The small amount of suspended material was collected by filtering through a celite bed whereas the bulk precipitated material at the bottom was collected by centrifugation. The total precipitate was dissolved in distilled water and clarified by centrifugation.

Step III (desalting). The dark-brown enzyme solution was desalted in batches by gel-filtration through a Sephadex G-25 or a Biogel P-6DG column using distilled water as eluant and then lyophilized to obtain an amorphous light-brown powder.

Step IV (ion-exchange chromatography). The enzyme powder was dissolved in a minimum volume of 50 mM-potassium phosphate buffer, pH 8.3, applied to a column (28 × 3 cm) of DEAE-Sephadex A-50 and eluted with 500 ml of the same buffer. Some protein, free from β-glucosidase activity, was removed in the buffer wash. The column was then washed with a salt gradient generated using 250 ml each of 0-1 M-NaCl in 50 mM-potassium phosphate buffer (pH 8.3) and 0.5 M-NaCl in the same buffer. Fractions containing β-glucosidase activity were pooled and the enzyme solution was desalted by gel-filtration as before. The colourless enzyme solution was concentrated by lyophilization.

Step V (gel-filtration). The protein from step IV, enriched in β-glucosidase, was dissolved in a minimum volume of 100 mM-ammonium acetate buffer, pH 5.6. The solution was chromatographed on an Ultrogel ACA-34 column and eluted with the same buffer. A large peak (U1) and a small peak (U2) of β-glucosidase activity were separated from some contaminating proteins. The enzyme solution (U1) was lyophilized, dissolved in 50 mM-sodium acetate buffer (pH 5.4) and stored at −20°C. This enzyme preparation was used in all experiments.

Protein estimation. The protein concentration of enzyme preparations was estimated according to the Lowry method using bovine serum albumin as standard. A_280 was used for monitoring protein in column effluents.

Electrophoresis. Disc gel electrophoresis of protein samples was done on 7% (w/v) polyacrylamide. Protein bands were stained with Coomassie brilliant blue R. In situ localization of β-glucosidase in the gel was accomplished by the procedure of Eilers et al. (1964). The gel was washed successively in distilled water, 500 mM- and 50 mM-sodium acetate buffer (pH 5.6) and then immersed in a staining solution which contained 10 mM substrate (cellulbiose or PNPG), 20 units glucose oxidase (Sigma, type VII), 4 mg nitroblue tetrazolium and 2 mg phenazine methosulphate in 10 ml 50 mM-sodium acetate buffer (pH 5.6). The gel was incubated at 45 °C and the enzyme was visualized as a blue band of insoluble formazan. The stained gel was stored in 7% (v/v) acetic acid.

Molecular mass determination. The molecular mass of β-glucosidase was estimated by gel-filtration through a column (75 × 1.5 cm) of Ultrogel ACA-34. The molecular mass protein markers were: horse spleen ferritin, 440 kDa; bovine liver catalase, 242 kDa; Aspergillus niger glucose oxidase, 154 kDa; bovine serum albumin, 66 kDa; and horseradish peroxidase, 40 kDa.

Molecular mass was also estimated by SDS-PAGE using the following molecular mass marker proteins: lysozyme, 14.4 kDa; α-lactoglobulin, 18.4 kDa; egg albumin, 45 kDa; bovine serum albumin, 66 kDa; and phosphorylase b, 97.4 kDa.

Transglycosylase activity. A mixture of β-glucosidase (500 ng) and substrate (1 mM) was incubated in 5 ml distilled water for up to 6 h at 50 °C. After boiling to stop the reaction, the solution was evaporated at reduced pressure and the residue was analysed by paper chromatography. The formation of a new AgNO₃-stainable spot was considered to result from transglycosylase activity.

Paper chromatography. Samples were chromatographed on Whatman no. 3 paper using butanol/ethanol/water (24:33:15, by vol.) for 24 h. The sugars were detected by the alkaline-AgNO₃ procedure.

Sugar estimation. Glucose was estimated by glucose oxidase-peroxidase method (McComb & Yushok, 1957). Cellubiose was estimated using S. thermophile β-glucosidase. For this, a sample was incubated with 0.2 unit β-glucosidase in 50 mM-sodium acetate buffer (pH 5.6) in a total volume of 1 ml for 60–90 min at 50°C. The glucose produced was quantified as above. Total sugar was estimated by the anithrone/H₂SO₄ procedure.

Chemicals. Sephadex G-25 and DEAE-Sephadex A-50 were from Pharmacia. Ultrogel ACA-34 was from LKB. Cello-oligosaccharides were from V-Labs. Nojirimycin was a gift from Dr Shigeharu Inouye, Meiji Seika Co., Yokohama, Japan. All other biochemicals were from Sigma.

Results

Multiple forms of β-glucosidases in S. thermophile

Polyacrylamide gel electrophoresis of culture filtrate protein and staining showed multiple β-glucosidases (Fig. 1). The protein bands corresponding to β-gluco-

*1 unit (U) = 1 μmol p-nitrophenol produced from PNPG min⁻¹ at pH 5.4, 50 °C.

Enzyme purification

Glucosidase in culture filtrate protein was adsorbed on DEAE-Sephadex at pH 8.3. The bulk cellulase was removed in the column wash. On further purification, a β-glucosidase activity was finally obtained with a specific activity of 80–90 U (mg protein⁻¹) (Table 1). Throughout the purification steps, the ratio of enzyme activity measured using PNPG or cellobiose as substrate remained constant. This showed that both aryl β-glucosidase and cellobiase activities were associated with the same protein. Electrophoresis of the final enzyme preparation showed a major protein band which coincided with a β-glucosidase activity band (Fig. 2).

The activity staining of β-glucosidase following PAGE gave an unexpected result. The activity-stained bands in culture filtrate samples containing lower β-glucosidase units were visualized faster (5 min) and were more prominent than in purified protein samples (15–30 min) which contained up to 10-fold higher β-glucosidase units. This discrepancy in β-glucosidase staining reaction between crude culture filtrate protein and purified enzyme was consistently observed with different batches.

Properties of β-glucosidase from S. thermophile

The temperature for maximum activity with either PNPG or cellobiose as substrate was close to 65 °C. There was no loss of activity when enzyme (50 μg ml⁻¹) was incubated in 50 mM-sodium/potassium phosphate buffer (pH 5.4) at 50 °C for up to 6 h, but at 60 °C, 25% of the original enzyme activity was lost after 2 h. At 70 °C, the enzyme activity was completely lost in 1 h. The activation energy calculated from the Arrhenius plot was 33.05 kJ (7.9 kcal) mol⁻¹.

The effect of pH on enzyme activity was studied using sodium acetate buffers (pH 3.5–5.4) or sodium/
potassium phosphate buffers (pH 5.4-8.2). The enzyme was most active in phosphate buffer at pH 5.2-5.4, at either 50 or 65°C, with PNPG or cellobiose. At 50°C, the enzyme was stable for at least 6 h at pH 4.0-6.5.

The molecular mass of native β-glucosidase was estimated to be 240 kDa. A single 110 kDa protein was found following SDS-PAGE, indicating that the native enzyme is composed of two similar subunits.

**Substrate specificity.** The enzyme hydrolysed aryl β-D-glucosides (phenyl β-D-glucoside, salicin, aesculin and amygdalin), β-1,4-, β-1,6- and β-1,3-linked diglucosides (cellobiose, gentiobiose and laminariobiase, respectively). The enzyme was also active on β-1,4-linked glucoligosaccharides (cellotriose, celtetraose, cellopentaose and cellohexaose) but it was totally inactive on β-1,4 glucan (Whatman filter paper, microcrystalline cellulose and carboxymethylcellulose). The relative activity of β-glucosidase on some substrates, based on the number of bonds broken per unit time, was (in parentheses): cellobiose (1), PNPG (1-9), gentiobiose (2-4), salicin (0-5) and aesculin (0-4). The purified enzyme may therefore be more appropriately designated as a β-aryl glucosidase. However, we have referred to it as β-glucosidase.

**Kinetics.** The effect of increasing concentrations of PNPG, cellobiose and gentiobiose on the initial velocity of β-glucosidase was studied. The reaction velocity increased with substrate concentration up to 1 mM. Higher concentrations of substrate inhibited enzyme activity. Lineweaver–Burk plots gave apparent $K_m$ values (mm) of 0.29, 0.83 and 0.35 for PNPG, cellobiose and gentiobiose (6-O-β-D-glucopyranosyl-D-glucopyranose), respectively.

**Inhibition of enzyme.** The effect of several sugars (10 mM) on β-glucosidase activity was studied using PNPG as substrate. The following inhibited β-glucosidase activity to the extent given in parentheses: D-glucose (80%), L-fucose (68%), D-maltose (65%). L-Arabinose, 2-D-deoxyglucose, D-galactose, D-glucose-6-phosphate, D-mannose, D-xylrose, lactose, lactulose (4-O-β-D-galactopyranosyl-D-fructose), melibiose (6-O-α-D-galactopyranosyl-D-glucose), palatinose (6-O-α-D-glucopyranosyl-D-fructose), sucrose and turanose (3-O-α-D-glucopyranosyl-D-fructose), inhibited activity by 10-30%. D-Fructose and trehalose (α-D-glucopyranosyl-α-D-glucopyranose) had no effect.

The type of inhibition caused by glucose was determined by assay of the enzyme with PNPG (0.05-1.0 mM) at fixed levels of glucose (0.5, 1.0, 2.0 and 4.4 mM). Double reciprocal plot of the data gave a series of lines intersecting at a common point on the y-axis, showing that glucose competitively inhibited the enzyme. The Dixon plot analysis gave a $K_i$ value of 0.5 mM.

Inhibition of enzyme by fucose was also competitive with a $K_i$ value of 2.6 mM. A double reciprocal plot of the initial velocity with varying concentration of PNPG (0.05-0.5 mM) at different fixed concentration of maltose (2, 4, 6, 8 and 10 mM) gave a series of parallel lines, indicating that inhibition of enzyme by maltose was uncompetitive, with a $K_i$ value of 2.4 mM.

Nojirimycin, an antibiotic which differs from glucose in the substitution of an NH group for oxygen in the ring, and gluconolactone have been reported as powerful inhibitors of β-glucosidases (Reese et al., 1971). Both compounds inhibited β-glucosidase of S. thermophile competitively. The $K_i$ values for nojirimycin and gluconolactone were 0.26 and 8.0 μM, respectively.

**Transglycosylase activity.** The ratio of glucose:aglycone released from hydrolysis of 0.5 mM-PNPG by β-glucosidase equalled one. This ratio decreased to 0.6 with 2-5 mM-PNPG. The decrease in amount of glucose produced with > 1 mM-PNPG indicated a parallel reaction in which the glycosyl moiety was transferred to an acceptor other than water. Paper chromatography of the reaction products showed a new AgNO₃-stainable spot which was absent in the control (enzyme not added). A transglycosylation product with a different $R_f$ was formed with cellobiose or gentiobiose.

The transglycosylation product formed using cellobiose was characterized as follows. Cellobiose (10 mM) and β-glucosidase (50 μg) were incubated in 500 ml distilled water at 50°C for 6 h and the reaction mixture was then lyophilized. The dried material was dissolved in a small volume of distilled water and chromatographed in two portions on a column of Bio-Gel P-2 (95 x 0.75 cm) using water as eluant. The fractions (1 ml) were assayed for total sugar, reducing sugar and glucose. Analyses showed three sugar peaks which corresponded to the elution volumes of the three carbohydrate markers (stachyose, cellobiose and glucose) used for calibration. The new product in the reaction mixture had an elution volume which corresponded to that of stachyose. This product was therefore considered to be a tetramer of glucose.

The fractions containing the putative transglycosylation product were pooled, concentrated and purified by paper chromatography. The material recovered gave 25 mg total sugar and 6 mg reducing sugar. This was in accord with the result of Bio-Gel P-2 chromatography, indicating that the transglycosylation product was a tetramer of glucose.

The action of β-glucosidase on the purified transglycosylation product was studied. Analysis of the reaction mixture at different time intervals by paper chromatography showed that the transglycosylation product was hydrolysed completely to glucose with the
intermediate formation of a dimer. The susceptibility of the transglycosylation product of \( S. \) \( \text{thermophile} \) \( \beta \)-glucosidase, which was shown to be specific for \( \beta \)-linked sugars, suggested that the glucose units were linked in the \( \beta \)-configuration.

**Effect of \( \beta \)-glucosidase on cellulase activity**

The effect of \( \beta \)-glucosidase on cellulase activity was studied by comparing the nature and quantity of the soluble products formed from hydrolysis of cellulose in the absence and presence of this enzyme. For this experiment, cellulase fractions designated F1, F2 and F3 were obtained from DEAE-Sephadex chromatography of 2-d-old culture filtrates (Fig. 3) which had low \( \beta \)-glucosidase activity. The samples were desalted and lyophilized before use. These cellulase fractions had negligible (F1 and F2) or very low (F3) contaminating glucosidase activity. The samples were desalted and lyophilized before use. These cellulase fractions had negligible (F1 and F2) or very low (F3) contaminating glucosidase activity.

After hydrolysis for 1 h, all cellulases released cellobiose as the principal (82–85\%) and glucose as a minor (5–11\%) soluble product from cellulose (Table 2). When \( \beta \)-glucosidase was added, cellobiose was quantitatively converted into glucose. In the presence of \( \beta \)-glucosidase, a substantially greater amount of sugar was produced by F3 cellulase (57\%) than by F1 (17\%) or F2 cellulase (10\%).

We examined whether the differential stimulation by \( \beta \)-glucosidase of cellulose hydrolysis by cellulase components of \( S. \) \( \text{thermophile} \) was due to a difference in their degree of susceptibility to cellobiose inhibition. Various concentrations of cellobiose were added to the reaction mixture under experimental conditions similar to those in Table 2. The amount of cellobiose added was subtracted from the measured value of total sugar. All the cellulases produced lower amounts of sugar upon addition of 100–1000 \( \mu \)g cellobiose as compared to the control. However, the decrease in the activity of cellulase was not proportional to the amount of cellobiose added in the reaction mixture. At 1000 \( \mu \)g (equivalent to that produced in the experiment in Table 2), cellobiose inhibited F1 cellulase by 23\%, F2 cellulase by 16\% and F3 cellulase by 35\%.

**Effect of β-glucosidase addition on cellulose hydrolysis by S. thermophile culture filtrates**

To examine and evaluate the influence of β-glucosidase on cellulose saccharification, cellulose hydrolysis was carried out for short (30 min) and long (24 and 48 h) periods. The culture filtrates possessed undetectable (day 1), low (day 2) or high (day 6) β-glucosidase activity (J. S. Gaikwad & R. Maheshwari, unpublished data). Cellulose saccharification with all culture filtrates increased with time of hydrolysis (Table 3). β-Glucosidase addition stimulated sugar production, the extent of stimulation being more with day 1 and day 2 than with day 6 culture filtrates. Paper chromatography of a control reaction mixture showed that a sugar with an Rf corresponding to that of cellobiose accumulated during the first 30 min of the reaction. Cellobiose accumulation was maximal with day 1 and minimal with day 6 culture filtrates, as judged by the intensity of stained spots on paper chromatograms. With β-glucosidase supplementation the ratio of reducing sugar to glucose nearly equaled unity at all times of incubation, indicating that glucose was the soluble product of cellulose hydrolysis by the culture filtrates.

To determine if the initially low ratio of glucose to reducing sugar in day 1 and day 2 culture filtrates was due to the inhibitory influence of accumulated cellobiose, hydrolysis of Whatman paper cellulose was carried out in presence of cellobiose. Additions of up to 100 μM-cellobiose were tolerated without appreciable inhibition of cellulase activity of the culture filtrates.

**Discussion**

A comparison of protein and activity staining of gels in Fig. 1 shows that β-glucosidases comprise the major proteins in 6-d-old culture filtrates of *S. thermophile* grown on cellulose as the carbon source. Very low extracellular β-glucosidase activity was found during the period of active growth when cellulase enzymes are secreted and cellulose is degraded (J. S. Gaikwad & R. Maheshwari, unpublished). This suggests that β-glucosidases are the major proteins which are released during autolysis in *S. thermophile* (J. S. Gaikwad & R. Maheshwari, unpublished). The β-glucosidase activity could be separated from the bulk culture filtrate protein by ion-exchange chromatography. From the data in Table 1 it was estimated that the purified β-glucosidase constituted approximately 6% of the extracellular protein in 6-d-old cultures of *S. thermophile* IIS 220 grown on cellulose. The purified β-glucosidase corresponded to the largest enzyme at the top of the gel in Fig. 1.

Our results differ from those of Canevascini & Meyer (1979), who did not find extracellular β-glucosidase in *S. thermophile*, irrespective of the carbon source (cellulose or cellobiose) used for growth. There are three possible reasons for this. First, Canevascini & Meyer used organic nitrogen alone for growth of the fungus. Organic nitrogen may repress the formation of β-glucosidase, as in *Schizophyllum commune* (Wilson & Niederpruem, 1967). Second, they incubated cultures for a short time (7–10 h) at lower temperature (44 °C). In *S. thermophile*, the maximum β-glucosidase is produced during idiophase (J. S. Gaikwad & R. Maheshwari, unpublished). Third, under identical conditions the enzyme productivity of strain ATCC 42464 used by Canevascini & Meyer is low, being about one-sixth that of our strain IIS 220 (Bhat & Maheshwari, 1987).

Meyer & Canevascini (1981) characterized two intracellular β-glucosidases from mycelia of *S. thermophile* (strain ATCC 42464) grown on cellobiose. A comparison of the characteristics of the two intracellular (Meyer & Canevascini, 1981) and extracellular β-glucosidases (this

study) shows that apart from their activity on β-glucosides, they are quite distinct (Table 4). For example, Meyer & Canevascini (1981) reported that one of the intracellular β-glucosidases (molecular mass 440 kDa) had only aryl-β-glucosidase activity when measured with o-nitrophenyl β-D-glucoside. This β-glucosidase was apparently not seen in our gels which were stained using PNPG as the substrate.

The pH and temperature optima, $K_m$ and molecular mass of extracellular β-glucosidase purified from S. thermophile are in agreement with the range of values reported for the enzyme from other fungal sources (Woodward & Wiseman, 1982). It is similar to other fungal β-glucosidases in catalysing the transglycosylase reaction, although the principal product formed from cellobiose was a tetramer rather than a trimer as in PNPG as the substrate.

β-Glucosidase from Sporotrichum thermophile 2831

be more susceptible to cellobiose (product) inhibition than F1 or F2 cellulases. The question is whether the stimulation of F3 cellulase activity by β-glucosidase was primarily because of the removal of cellobiose inhibition. The data in Table 3 show that β-glucosidase stimulation of cellulase activity cannot be explained purely by the relief of cellobiose inhibition. First, after cellulose hydrolysis for 30 min by day 1 culture filtrates containing undetectable β-glucosidase, cellobiose accumulated to approximately 12 μg ml⁻¹ (35 μM) in reaction mixtures. However, under these conditions cellobiose concentrations higher than 100 μM were required to significantly inhibit culture filtrate cellulase activity. Second, addition of β-glucosidase also stimulated cellulase saccharification when there was no accumulation of cellobiose. For example, in the control reaction mixtures at 24 and 48 h, the ratio of glucose to reducing sugar was almost unity; yet β-glucosidase addition resulted in increased sugar production. These observations may be explained on the basis of a 'combination theory' which postulates that a multi-enzyme complex of β-glucosidase with other cellulase components allows a coordinated catalysis of a complex reaction and enhances the rate of cellulose hydrolysis (Joglekar et al., 1983; Sprey & Lambert, 1983). Sadana & Patil (1985) reported a synergism between cellulases and β-glucosidases of Sclerotium rolfsii which appears to result from a protein–protein interaction rather than from removal of cellobiose inhibition. We used an aryl-β-glucosidase simply because this enzyme could be purified in sufficient quantity for experimentation. However, it could be that true cellobioses potentiate cellulase activity to a greater extent than the β-glucosidase used in this study.

This investigation was supported by Council of Scientific & Industrial Research and University Grants Commission, New Delhi.
