(Received 20 February 1992; revised 19 October 1992; accepted 20 October 1992)

The anchoring (irreversible attachment) of *Azospirillum brasilense* Cd to hydrophobic polystyrene and to root surfaces was compared. Live *A. brasilense* Cd cells attached in significantly greater numbers to roots than to polystyrene, regardless of treatments made to the surfaces or to the bacterial cells. Triton X-100, Na₂EDTA and several bacterial-inhibitory substances reduced bacterial attachment to both surfaces, although this effect was greater with attachment to polystyrene than to roots. Pre-coating with root exudates, bovine serum albumin or gelatin significantly increased anchoring to both surfaces. Manganese-limited cells showed increased anchoring to roots, whereas dead cells adsorbed better to polystyrene. Although the anchoring of *A. brasilense* Cd to a non-biological surface can be significantly altered by using several promoting or inhibiting substances to affect the properties of both the surface and the bacterial cell, anchoring to root surfaces is less affected by these substances. It is proposed that at least two different quantitative types of anchoring exist in this bacterium: a sparse attachment to a non-biological surface and a prolific attachment to roots.

Introduction

Efficient root colonization is a major factor when assessing the effect of beneficial plant-associated bacteria (Bashan & Levanony, 1990). *Azospirillum* species are able to colonize root surfaces of a wide variety of plant species (Bashan et al., 1989), the interior cortex of cereal roots (Levanony et al., 1989), isolated cells (Eyers et al., 1988), or synthetic inoculants (Bashan, 1986b). They are distributed along the root system (Baldani et al., 1986), but are concentrated mainly in the elongation and root-hair zones (Bashan et al., 1991).

*Azospirillum* is able to colonize roots permanently and irreversibly for extended periods (Bashan et al., 1987; Harris et al. 1989). Colonization occurs mainly on the root surfaces (and to a lesser extent on root hairs) by means of extensive formation of fibrillar material which connects the bacterial cells to the roots irreversibly (Levanony & Bashan, 1991). The fibrils which form have been defined as being proteinaceous or polysaccharide in nature (Bashan & Levanony, 1988b; Michiels et al., 1991). However, the mechanism of attachment is, as yet, not completely resolved. It has been speculated that these fibrils contain receptors to plant agglutinins and lectins (Bashan & Levanony, 1988c; Del Gallo et al., 1989; Madi & Henis, 1989). Lectins have been implicated in *Rhizobium* recognition and attachment to plant host cells (Smit & Stacey, 1990). To date, attachment of *Azospirillum* to roots has not been compared with attachment to other hydrophobic surfaces which are commonly used to evaluate the attachment of bacteria responsible for biofouling in other environments (Fletcher, 1977; Klotz, 1990).

Michiels et al. (1991) proposed two different modes of attachment of *Azospirillum brasilense* to wheat roots, similar to those previously proposed by Marshall (1986) for the attachment of soil bacteria to soil particles. The primary absorption phase is fast, weak and governed by proteinaceous compounds as described previously by Bashan & Levanony (1988b). The second phase (called anchoring) is stronger, irreversible and probably based on surface polysaccharides (Michiels et al., 1990). The anchoring phase, characterized by the production of long fibrils, has been observed in roots of several crop plants (Bashan et al., 1991) and is probably the major factor in effective root colonization which ultimately enhances plant growth (Bashan, 1986a; Bashan et al., 1989).

Abbreviations: ANOVA, analysis of variance; TTC, triphenyl-tetrazolium chloride.
The aims of this study were: (i) to investigate the anchoring phase of *A. brasilense*, and (ii) to establish its preference for living, heterogeneous surfaces such as roots. Comparisons were made of anchoring to roots and to a uniform polystyrene surface under diverse environments and surface treatments.

**Methods**

Organisms and bacterial growth conditions. The rhizosphere bacterium *Azospirillum brasilense* Cd (ATCC 29710) and wheat seedlings (*Triticum aestivum* cv. Tikal; winter wheat) were used. Bacteria were grown and prepared for inoculation as described previously (Bashan & Levanony, 1985). The cultures were grown for 16 h at 30 ± 1 °C in OAB N-free medium of the following composition. Solution A: (g l⁻¹) DL-malic acid, 5; NaOH, 3; MgSO₄, 7H₂O, 0.2; CaCl₂, 0.02; NaCl, 0.1; NH₄Cl, 1; yeast extract, 0.1; FeCl₃, 0.01; (mg l⁻¹) NaMoO₄, 2H₂O, 2; MnSO₄, 2H₂O, 0.25; HBO₃, 2.8; Cu(NO₃)₂, 3H₂O, 0.04; ZnSO₄, 7H₂O, 0.24; 900 ml distilled water. Solution B: (g l⁻¹) KH₂PO₄, 6; KH₂PO₄, 4; 100 ml distilled water. After separate autoclaving and cooling, the two solutions were mixed and the pH was adjusted to 6.8 with NaOH (Okon et al., 1977). To avoid self-aggregation, the bacteria were grown in Erlenmeyer flasks with shallow grooves, shaken at 250 rpm. For 16 h. This allowed the harvesting of non-aggregated bacteria in the exponential phase of growth. Carbon- or manganese-limited cells were obtained by transferring double-washed cells grown in OAB medium into an identical medium with either 0.1 mM-NaCl (PBS), 20 mM-fructose and 50 mM-NH₄Cl. Under these conditions, the bacteria are able to multiply and produce abundant amounts of fibrillar material. The suspension was adjusted to 1 x 10⁸ c.f.u. ml⁻¹ (or an equivalent number of dead cells), was used only once in experiments designed to count bacteria by the ELISA technique, which has a detection threshold of 10⁴ c.f.u. ml⁻¹ or more, without differentiating between live or dead cells (Levanony et al., 1987). Colonization was measured on the root-surface of the root hair zone.

Pre-coating of roots, bacteria and polystyrene. Prior to inoculation, roots and polystyrene surfaces were coated by dipping (Petri dishes) with PBS solution supplemented with the following substances: Triton X-100 (Rohm and Hass) at 10 μl l⁻¹, streptomycin sulphate (Sigma) at 200 mg l⁻¹, 2,3,5-triphenyltetrazolium chloride (TTC) (Riedel de Haen) at 15 mg l⁻¹, neomycin sulphate (Sigma) at 200 mg l⁻¹, KCN at 5 or 100 mg l⁻¹; methyl violet at 60 mg l⁻¹, tetracycline (Sigma) at 200 mg l⁻¹, chloramphenicol (Sigma) at 250 mg l⁻¹; root exudates at 100 mg ml⁻¹ (Gafni et al., 1986), or 1 mM Na₂EDTA. The following proteins were used at 0.2%: bovine serum albumin (BDH), gelatin (type A, Sigma), fibrinogen (from bovine plasma, type I-S, Sigma), pepsin (Sigma) and histone (type III-S, Sigma). Pepsin had no enzymatic activity under the conditions described above, as it is only active at acidic pH (Fletcher, 1976). Histone was dissolved in acidified distilled water (Fletcher, 1976). All materials except histone and KCN left the dish surface completely wettable, indicating the formation of an adsorbed film. After 2 h incubation at ambient temperature, the solutions were pumped out by a small vacuum pump equipped with a Pasteur pipette. *A. brasilense* Cd suspensions were immediately added to the wet surfaces. Additional controls were dishes treated with each of the materials and stained, but not inoculated.

In additional experiments, the bacterial culture was treated with the final concentrations of substances listed above 3 h before extraction of bacteria from the culture for the attachment assays.

**Dead bacteria**. Bacteria were killed either by heat treatment (30 min. 100 °C) or by fixation with 5% glutaraldehyde (v/v), final concentration) for 2 h at 25 ± 2 °C. The dead bacteria were rinsed twice with PBS before they were used in the attachment assay. Dead bacteria were counted by the indirect-ELISA technique (Levanony et al., 1987).

Experimental design and statistical analysis. All experiments were done with five replications per treatment. A replicate consisted of three root segments or Petri dishes. Numerous scanning spectroscopic determinations were performed on every dish, eventually covering the entire surface of the dish. All experiments were repeated twice, and data from both experiments were used for statistical analysis. Results were
Results

Anchoring of A. brasilense Cd to polystyrene and to wheat roots after different incubation times

The anchoring of A. brasilense Cd to roots was greater than that to polystyrene (Fig. 1). Anchoring to roots rapidly increased to its maximum after incubation for 48 h and remained constant thereafter. Anchoring to polystyrene also increased with time, but more slowly. The ratio of bacterial attachment between root and polystyrene thus decreased from 1.9:1 to 1.2:1 between 24 h and 72 h (Fig. 1).

Effects of a surfactant, antibiotics and bacterial-inhibitory substances on anchoring to roots and polystyrene

Application of the bacterial-inhibitory substances (with the exception of streptomycin sulphate) and Triton X-100, either to the bacterial culture or to polystyrene and root surfaces, reduced the anchoring of bacteria to both surfaces (Fig. 2a, b). Treatment of the bacterial culture with Triton X-100, TTC, methyl violet, tetracycline, chloramphenicol or a high concentration of KCN prior to the attachment assay almost eliminated anchoring to the surfaces. Anchoring of treated bacteria to both roots and polystyrene was less inhibited by neomycin sulphate and a lower concentration of KCN (Fig. 2a).

When the same inhibitory substances were spread on polystyrene and root surfaces prior to bacterial inoculation, a different response was observed. The substances reduced anchoring to polystyrene significantly more than anchoring to roots (Fig. 2b). Untreated bacteria attached better to treated root surfaces than treated bacteria attached to untreated surfaces.

Effects on anchoring of pre-coating the surfaces with proteins, root exudates, or Na₂EDTA

When roots or polystyrene surfaces were coated with various proteins, inoculated with A. brasilense Cd, and then incubated, two of the proteins, bovine serum albumin and gelatin, significantly increased bacterial anchoring to both surfaces. Anchoring levels for all treatments, regardless of their effectiveness, were greater to roots than to polystyrene (Fig. 3a, b). The treatment of both surfaces with root exudates significantly increased anchoring, whereas the Na₂EDTA treatment almost

Fig. 3. Anchoring of A. brasilense Cd to root and polystyrene surfaces after the bacteria (a) or the surfaces (b) were treated with various proteins, root exudates or Na₂EDTA prior to the anchoring assays. Columns with a different lower-case letter (panels a and b) considered separately differ significantly from each other at \( P < 0.05 \) in a one-way ANOVA. Ratios of bacterial anchoring (in cells) between roots and polystyrene surfaces are shown for each treatment. ■, Anchoring to roots; □, anchoring to polystyrene; ◼, anchoring to roots after treatment; ◼, anchoring to polystyrene after treatment.

eliminated anchoring (Fig. 3b). When the proteins were added to bacterial cultures prior to inoculation, they had no significant effect on the resulting anchoring. Na₂EDTA retained its negative effect and root exudates retained their positive effect (Fig. 3a).

### Attachment of dead A. brasilense Cd cells to roots and polystyrene

Killing the bacteria prior to application to the roots almost abolished attachment: only 0.1--0.13% of the original population attached. Killing the bacteria had a lesser effect on attachment to polystyrene: 5--12.8% of the original population attached to the surface (Table 1). Coating the polystyrene with various proteins prior to applying the dead bacteria had no effect on the amount of attachment, regardless of the treatment (Table 2).

### Effect of manganese and carbon limitations on anchoring

Manganese-limited cells anchored better to roots than did non-limited cells, but they anchored less well than non-limited cells to polystyrene (Fig. 4). Carbon-limited cells anchored less well than non-limited cells to both

roots and polystyrene; however, the ratio was higher than for normal cells (Fig. 4).

Discussion

Bacterial attachment appears to have two distinct phases: (i) reversible adhesion based mainly on physicochemical bonds (ionic, hydrophobic) which are usually weak, non-specific and allow the cells to be easily detached from roots, and (ii) irreversible attachment, or anchoring, in which the bacteria–surface interaction forms a network of substances which permanently binds the bacteria to the surface (Marshall, 1986). Although the attachment of *A. brasilense* to roots has these two phases (Michiels et al., 1991), long-term colonization and rhizocompetence is based mainly on the anchoring phase of the attachment process (James et al., 1985).

The secure attachment of beneficial bacteria is essential for a long-term association with the host plant for three reasons. (i) If the bacteria are not attached to root epidermal cells, substances extracted by the bacteria diffuse into the rhizosphere, where they are consumed by nutritionally-versatile micro-organisms before reaching the target plant. However, when the bacteria attach to the roots, part of these substances are diffused from their longitudinal side into the intercellular spaces of the root cortex. This is especially true for bacterial aggregate colonization where attachment is horizontal to the root surface (Levanony et al., 1989). (ii) Without a secure attachment, water may wash the bacteria away from the rhizosphere to perish in the surrounding, nutrient-deficient soil. *Azospirillum* is known to survive poorly in soils without plants to act as hosts (Bashan & Levanony, 1990). (iii) Association sites on roots with no attached beneficial bacteria are vulnerable to other aggressive, non-beneficial colonizers.

Bacterial attachment can be specific, as in *Rhizobium*–legume interactions (Smit & Stacey, 1990) or non-specific as in the case of *Azospirillum*, which is capable of attachment to nearly every root system tested so far (Bashan & Levanony, 1990). The present study focused on the anchoring phase of *A. brasilense* attachment both to roots and to polystyrene surfaces; both these surfaces are primarily hydrophobic in nature. These two surfaces were compared to evaluate the significance of both the bacteria and the surface on the anchoring phase. The differences in the anchoring ratios between the root and polystyrene surfaces reflect the effect of surface properties on the anchoring process.

The attachment of bacteria to surfaces is affected by various physicochemical factors of the cell and the surface (Fletcher & Loeb, 1979), and by culture variables of concentration and age (Fletcher, 1977). Surface-active agents, antibiotic treatments or surface protein coatings reduce hydrophobic interactions, and in so doing reduce microbial adhesion to plastics (Fletcher, 1976; Klotz, 1990). Although these factors were considered important in the reversible adhesion phase (Fletcher & Loeb, 1979), the present study demonstrates that they affect the anchoring phase as well. As expected, most substances applied to polystyrene surfaces inhibited the anchoring of *A. brasilense* Cd. However, when these substances were applied to roots, their inhibitory effect was smaller, probably because the metabolic activity of the roots inactivated a proportion of the substances.

A surprising result was the effect of two proteins, bovine serum albumin and gelatin, both of which are known to inhibit the primary bacterial adhesion of marine bacteria (Fletcher, 1976). In this study, the application of these proteins increased anchoring of *A. brasilense* Cd to both surfaces. Fibrinogen and pepsin also increased anchoring, but only to polystyrene. The reason for this phenomenon is still unclear. It is possible that the proteins served as a nutrient source for the applied bacteria, creating a larger bacterial population which attached to the surfaces only after most of the proteins were consumed. This hypothesis is indirectly supported by the fact that pre-coating polystyrene with these proteins did not increase the attachment of dead bacteria.

It has been shown that for *Azospirillum* to colonize roots, bacterial metabolism is far more important than the surface properties of the roots; live bacteria attached well to dead roots, but dead bacteria attached less to live roots (Bashan et al., 1986). In this study, dead bacteria attached better to polystyrene than to roots, providing further support for the hypothesis that the primary adhesion mechanism of *A. brasilense* is physicochemical in nature, rather than biological as was suggested for many bacterial species (Cope, 1980).
Rhizobium is known to produce fimbriae which participate in the attachment to the plant. This attachment is greatly affected by the nutritional status of the bacterial cells prior to inoculation, and especially by carbon and manganese limitations (Kijne et al., 1988; Smit & Stacey, 1990). Our study provides preliminary evidence that, as observed for Rhizobium leguminosarum, manganese-limited cells of A. brasilense Cd anchor better to roots than do normal cells. Unlike rhizobia, the anchoring of carbon-limited cells of A. brasilense Cd to roots and polystyrene was less than for non-treated bacteria.

The preference of A. brasilense, a terrestrial bacterium, for living surfaces is surprising in view of the fact that medical and marine biofouling is pervasive on non-living surfaces. The skin of many marine mammals resists bacterial attachment throughout their life in a bacteria-rich environment. The attachment of bacteria within the human body to plastic medical implants in preference to surfaces. The skin of many marine mammals resists anchoring to the root surface is less affected by these characteristics on the attachment of a marine pseudomonad to solid surfaces. In Adsorption of Microorganisms to Surfaces, pp. 105-144. Edited by G. Bitton & K. C. Naylor. New York: Wiley-Interscience.

In conclusion, the anchoring of A. brasilense Cd to a non-biological surface can be significantly altered by using several promoting or inhibiting substances to affect the surface properties and the bacterial cell. Nevertheless, anchoring to the root surface is less affected by these substances. We propose that at least two different quantitative types of anchoring exist for this bacterium: a sparse attachment to a non-biological surface and a prolific attachment to roots.
