(Received 9 September 1992; revised 3 December 1992; accepted 18 December 1992)

The *rpmB,G* operon of *Escherichia coli* codes for the synthesis of ribosomal proteins L28 and L33. In one mutant strain (TP28), these two proteins are made at about half their normal rates, ribosome assembly is greatly perturbed and precursor particles accumulate. The mutation in strain TP28 is in a Shine–Dalgarno sequence in the leader region of the *rpmB,G* messenger RNA. Another mutant, strain AM108, makes neither protein because it has the mobile element IS1 inserted into the *rpmB* coding sequence. Surprisingly, ribosome assembly in this strain is virtually normal with respect to growth rate. Strain AM90, which fails to make protein L33, has the element IS3 inserted into *rpmG* and also shows no major defects in ribosome assembly.

Introduction

Ribosome assembly in *Escherichia coli* involves co-ordinated synthesis of three ribosomal RNAs and over fifty ribosomal proteins. Rates of synthesis of the ribosomal RNAs adjust to the medium in which organisms are growing; in extreme circumstances, synthesis is shut off if organisms are starved of an amino acid. A number of control mechanisms is involved whose apparent redundancy implies that regulation is still possible if one is inactivated (Ross et al., 1990). There is transcriptional control of ribosomal protein synthesis but the final adjustment of rates is usually by regulation of translation of the ribosomal protein operons (Lindahl & Zengel, 1986). Often, a protein of an operon that binds directly to ribosomal RNA during ribosome assembly also binds, more weakly, to the leader region of its messenger RNA and, if in excess, inhibits translation of all the proteins of the operon.

A consequence of co-ordinated synthesis is that only 2–5% of the ribosomal RNA of exponentially-growing cells is in ribosomes in course of synthesis (Lindahl, 1975). The pools of most ribosomal proteins un-associated with RNA are also small (Ulbrich & Nierhaus, 1975). In a number of circumstances, though, ribosome assembly can be disturbed so that precursor particles accumulate. Organisms treated with low concentrations of protein-synthesis inhibitors accumulate ribosome precursors akin to those detected in exponentially-growing cells. Some conditional mutants accumulate precursor particles at restrictive temperatures. Assembly can be defective without conferring a cold- or temperature-sensitive phenotype; for example, some strains that have reverted from erythromycin-dependence show un-balanced synthesis of RNA and protein and accumulate ribosome precursors during slow exponential growth (Wild, 1988).

*E. coli* strain TP28, another example of an organism with defective ribosome assembly, accumulates unusual '47S' particles during exponential growth at 37 °C. The assembly mutation was shown to be near, and probably within, the *rpmB,G* operon that codes for ribosomal proteins L28 and L33; both proteins are made at about half their normal rates (Butler & Wild, 1984, 1985). The mutation has other consequences. The 47S particles lack proteins L28 and L33 and have substoichiometric amounts of at least three others, L16, L25 and L27. Synthesis takes place as though the particles, rather than 50S subunits, are the end products (Butler et al., 1979, 1980). Thus, at 20 °C, there are three sequential precursors to 47S particles analogous to the three precursors to the 50S subunits of the parent strain. The 47S particles subsequently acquire the proteins they lack to become the 50S subunits of 70S ribosomes. The latter now have a complete set of ribosomal proteins but function poorly in protein synthesis (Sims & Wild, 1976).

The present work shows that the assembly mutation in strain TP28 is a single base change in the putative Shine–Dalgarno sequence of a ribosome-binding site in the leader region of the mRNA for proteins L28 and

Abbreviation: m.g.t., mean generation time.
L33. In addition, the work examines two other strains, AM90 and AM108, whose parent is strain AM, an erythromycin-dependent derivative of *E. coli* strain A19 (Dabbs, 1979). Spontaneous revertants of strain AM to erythromycin independence are often organisms in which failure to make one or more ribosomal proteins suppresses the dependency. Ribosomes from strain AM90 lack ribosomal protein L33 while those from strain AM108 have neither L28 nor L33; cross-reacting material is also absent (Dabbs et al., 1983). Our expectation was that these strains, particularly AM108, would have similar (or greater) defects in ribosome assembly than strain TP28. However, this is not the case. Possible reasons for this are discussed. The mutations in strains AM90 and AM108 are identified.

**Methods**

**Bacteria and media.** The strains of *E. coli* used were (i) 15 thy pro (15TP) and the mutant 15-28 (TP28) derived from it; (ii) two transductants of the K12 strain RE74; in RE74-807, *pyrE* and the linked ribosome mutation have been transferred from TP28, while in RE74-803, *pyrE*, but not the ribosome mutation, is present (Butler & Wild, 1985); (iii) strain A19 (Gesteland, 1966), the erythromycin-dependent strain, AM, derived from A19, and two revertants to erythromycin-independence, strains AM90 and AM108 (Dabbs, 1979); (iv) revertants to erythromycin-independence (strains R1, R5, R10 and R15) of the erythromycin-dependent strain 103 (Wild, 1988).

Bacteria were grown in liquid media with shaking at 37 °C. The media were as follows. (i) DP-broth, which contained, per litre, 10 g tryptone, 10 g yeast extract, 5 g glucose, 3 g KH2PO4, 7 g K2HPO4, 500 mg trisodium citrate and 200 mg MgSO4.7H2O. (ii) Tris-buffered amino acid (TAA) medium; this contained, per litre of 0.1 M-Tris/HCl pH 7.4, 2 g glucose, 2 g KCl, 2 g NH4Cl, 500 mg MgCl2, 6H2O, 178 mg Na2HPO4, 50 mg Na2SO4, 2 mg Fe(NH4)2(SO4)2, 6H2O, 8 mg uracil and 40 mg each of 19 l-amino acids (the set of 20 without lysine). TAA medium (with lysine added as below) was used when subsequent analysis was of ribosome assembly or of ribosomal proteins. (iii) L-broth, which contained, per litre, 10 g tryptone, 5 g yeast extract, 5 g NaCl, 1 g glucose and 30 mg L-cysteine. HCl, and supplemented as appropriate with 60 mg ampicillin and/or 50 mg tetracycline. This medium was used for maintenance and selection of plasmids and when DNA was subsequently isolated.

Detection of ribosomes and ribosome precursor particles. [$^3$H]Uracil and/or [$^{14}$C]Uracil were used to label RNA during growth in TAA medium containing 40 μg lysine ml$^{-1}$. Harvested organisms were washed in 10 mM-Tris/HCl, pH 7.4, containing 10 mM-magnesium acetate (THM buffer) and resuspended in THMKsp buffer (THM buffer plus 100 mM-KCl and 1 mM-mercaptoethanol). HCl). Extracts were made and density-gradient centrifuging done as previously (Wild, 1988).

Synthesis of ribosomal proteins by strain AM108. For pulse-chase experiments, carrier-free [$^{3}$H]lysine (84 Ci mmol$^{-1}$; 7.5 μCi ml$^{-1}$) was added at OD$_{450}$ 0.3 to cultures growing exponentially in TAA medium without lysine, followed, after 2 min, by non-radioactive lysine (final concn 1 mg ml$^{-1}$). Samples (10 ml) taken at 4 min and later were poured onto crushed ice and 10 ml of a reference culture (strain AM108 labelled for two generations with [$^{14}$C]lysine [0.2 μCi (74 kBq) and 5 μg ml$^{-1}$]) added. Harvested bacteria were washed, resuspended in buffer, broken in a French pressure cell and ribosomal proteins extracted with acetic acid; the methods, the subsequent electrophoresis in the 'standard' buffer system and the assay of radioactivity in protein spots were as previously (Butler & Wild, 1984). The ratios of radioactivities in protein spots were normalized (Dennis, 1974): for protein i, the ratio $A_i = (^{3}H/^{14}C$ in protein i)/($^{3}H/^{14}C$ in total ribosomal protein).

**DNA manipulations.** Unless noted below, standard procedures were used (Sambrook et al., 1989). Chromosomal DNA was isolated from bacteria grown in L-broth. The polymerase chain reaction (PCR) was used to amplify DNA of the rpmB,G operon. The primers were made in the Dyson Perrins Laboratory, Oxford. Primer 1 was AAATTGAAATTCGCGATGCGGATCTT, with five flanking nucleotides at the 5' end, an EcoRI restriction site (underlined) and 20 nucleotides complementary to the non-coding strand at the 5' end of the published sequence (Lee et al., 1981; their numbering is used throughout this paper). Primer 2 was TAGTAAAGTCGGGTA-ATTCCGCACTAGCA, with a flanking zone, a HindIII site and 20 nucleotides complementary to the coding strand at the 3' end of the sequence. The PCR was run for 30 cycles with a Perkin-Elmer heating block and used 0.1 μg chromosomal DNA and 0.01 μg of each primer per reaction mixture (100 μl). The products were run on a 1% (w/v) agarose gel and a designated DNA band collected by electroelution. The DNA, recovered by ethanol precipitation, was ligated into plasmid pTZ18R (from Dr K. G. H. Dyke, Microbiology Unit, University of Oxford) after digestion of both fragment and vector with EcoRI and HindIII. The products were transformed into *E. coli* strain JM109. Sequencing was with the Sequenase 2.0 kit and the 'Sequencing' and 'Reverse Sequencing' primers (from Boehringer-Mannheim); two other 18-nucleotide primers that corresponded to sequences (or their complement) within the operon were used to help sequence the operon from strains AM90 and AM108.

**lac fusions.** These were made from PCR-generated mRNA leader sequences. For the leader from strain 15TP, the source of DNA was the rpmB,G operon cloned into pTZ18R; the primers were (a) the same as the sequence from nucleotides -216 to -199, and (b) the complement of nucleotides -114 to -3. The product therefore included the promoter for the rpmB,G operon, the Shine-Dalgarano sequence and the first three translated nucleotides (ATG). For strain TP28, the second primer was one nucleotide different so as to complement the altered Shine-Dalgarano sequence. The products were blunt-end ligated into plasmid pU1553A (kindly given by Dr S. Kaplan, Department of Microbiology, University of Texas) cut with HindIII. The DNA, recovered by ethanol precipitation, was ligated into plasmid pTZ18R (from Dr K. G. H. Dyke, Microbiology Unit, Oxford University) cut with HindIII and EcoRI. The products were transformed into *E. coli* strain JM109. Sequencing was with the Sequenase 2.0 kit and the 'Sequencing' and 'Reverse Sequencing' primers (from Boehringer-Mannheim); two other 18-nucleotide primers that corresponded to sequences (or their complement) within the operon were used to help sequence the operon from strains AM90 and AM108.

**Results**

**Assembly of ribosomes**

Strains A19, AM90, AM108, 15TP and TP28 were grown in DP-broth to OD$_{450}$ 0.5. The dependent strain, AM, was grown similarly but with 100 μg erythromycin ml$^{-1}$. Extracts were made and centrifuged through sucrose gradients (Fig. 1a-f). The two parent strains, A19 and 15TP, have normal profiles, with native 30S and 50S subunits present in small quantities relative to 70S
Effect of rpmB,G mutations on ribosome synthesis

Fig. 1. Sedimentation profiles of ribosomal particles from wild-type and mutant strains after sucrose-density gradient centrifugation. Extracts were made from (a) strain A19, (b) strain AM (after growth with 100 μg erythromycin ml⁻¹), (c) strain AM90, (d) strain AM108, (e) strain 15TP and (f) strain TP28.

Fig. 2. Sedimentation profiles of mixed extracts from strains TP28 and AM108. Strain TP28 was grown from OD₆₅₀ to 0.05 to 0.50 in DP-broth containing [³H]uracil [1 μCi (37 kBq) ml⁻¹]; strain AM108 was grown similarly but with [¹⁴C]uracil [0.1 μCi (3.7 kBq) ml⁻¹]. Extracts made with a French pressure cell were mixed and centrifuged. Panel (a) shows the complete profile from the gradient; in (b), a portion of (a) is redrawn to show more clearly the different sedimentation properties of 47S particles from strain TP28. ○, ³H radioactivity; ●, ¹⁴C radioactivity.

Ribosomes. The profile from strain TP28 shows, as previously reported (Butler & Wild, 1984), three ribonucleoprotein components in similar amounts. The 30S material is a mixture of 30S ribosomal subunits and a precursor to them (Markey & Wild, 1975); the ‘47S’ particles are abnormal precursors to 50S ribosomal subunits that sediment more slowly than the subunits.

The profile of strain AM (Fig. 1b) shows fewer 50S ribosomal subunits than its parent, strain A19, while the 30S subunits have a shoulder of faster-sedimenting material. These changes are a consequence of growth with erythromycin, which, like other antibiotics that inhibit protein synthesis, uncouples RNA and protein synthesis and so alters ribosome assembly (B.A.
Maguire & D. G. Wild, unpublished observations). The profile of strain AM90 shows more 30S and 50S material than strain A19, probably because strain AM90 grows rather slowly (m.g.t. 54 min). The 30S and 50S material is more marked in the profile of strain AM108 (m.g.t. 172 min; Fig. 1d). Even so, strain AM108 shows none of the gross alterations characteristic of strain TP28; the areas under the 30S and 50S peaks are together about 50% of that under the 70S ribosomes; for strain TP28, the figure is 170%.

Other comparisons were made between strains TP28 and AM108. (i) The two strains were grown in DP-broth with [3H]uracil (strain TP28) or [14C]uracil (strain AM108). Extracts were made, mixed and sedimented through the same gradient. The sedimentation profiles (Fig. 2) confirm the excess of 30S and 47S material in strain TP28 and show that the 47S particles of strain TP28 sediment appreciably more slowly than the 50S material of strain AM108.

(ii) Ribosome assembly by strain AM108 was examined by pulse-labelling. As a control, strain A19, grown (m.g.t. 36 min) in TAA medium with [14C]uracil, was pulse-labelled with [3H]uracil. Fig. 3(a, b) shows sedimentation profiles of samples taken after 30 s and 1 min (1.5 and 3% of a generation). The steady-state 14C profiles show tRNA, 30S and 50S subunits and 70S ribosomes; polysomes, present in extracts prepared by gentle lysis, have sedimented. The pulse label shows ribosomes in course of synthesis. At 30 s, the p50S-1 precursor to 50S ribosomal subunits (Lindahl, 1975) is more apparent than its product, the p50S-2 precursor particle; at 1 min, this situation is reversed. A similar experiment (Fig. 3c, d, e) with strain AM108 had labelling times (4 min 25 s, 6 min 35 s and 8 min 50 s) equivalent to 2, 3 and 4% of a generation. The earliest sample shows only a p50S-1 precursor to 50S ribosomal subunits; subsequently, a 50S-2 precursor is evident. Another experiment with strain AM108 measured the 3H radioactivity from a pulse-label associated with 70S ribosomes at different times; the break in the curve (Fig. 3f) is when newly-made rRNA begins to enter 70S ribosomes. For strain AM108, this 'ribosome maturation time' is about 20 min; that for strain A19 (experiment not shown) is about 3 min. These times are 9 and 8% of the mean generation times of the organisms. Comparable figures are also obtained with strains AM (7%) and AM90 (10%). This constancy is similar to that shown by a strain of E. coli 15 grown at different rates in various
media (Michaels, 1972) and is thus that expected for normal ribosome assembly.

Ribosome assembly by strain AM108 is thus very similar to that in strain A19. This contrasts sharply with strain TP28, where synthesis proceeds as though 47S particles, rather than 50S ribosomes, are the end product of the pathway (Butler et al., 1979, 1980). Moreover, the ribosome maturation time is 20% of the m.g.t. in a range of growth media (R. Skelt & D. G. Wild, unpublished observations).

**RNA content of strains**

The RNA contents of strains A19, AM, AM90 and AM108 were compared by growing the strains in portions of the same batch of DP-broth containing [3H]lysine [2 μCi (74 kBq) ml⁻¹] and [14C]uracil [0.02 μCi (74 kBq) ml⁻¹] added. Strain AM and a second culture of strain A19 (indicated by +Spc) were grown identically but with 5 μg spectinomycin ml⁻¹. At OD₅₅₀ 0.50, three samples (1.0 ml) were taken from each culture for estimation of radioactivity insoluble at 0 °C in 5% (w/v) trichloroacetic acid.

![Graph showing RNA content of revertant strains](image)

Fig. 4. RNA content of revertant strains. The strains indicated were inoculated (OD₅₅₀ approx. 0.05) into portions of the same batch of DP-broth with [3H]lysine [2 μCi (74 kBq) ml⁻¹] and [14C]uracil [0.02 μCi (7-74 kBq) ml⁻¹] added. Strain AM and a second culture of strain A19 (indicated by +Spc) were grown identically but with 5 μg spectinomycin ml⁻¹. At OD₅₅₀ 0.50, three samples (1.0 ml) were taken from each culture for estimation of radioactivity insoluble at 0 °C in 5% (w/v) trichloroacetic acid.

**Nature of the mutations**

Chromosomal DNA was prepared from strains A19, AM, AM90, AM108, 15TP and TP28. DNA encoding the rpmB,G operon was amplified by PCR. The products were ligated into plasmid pTZ18R. The inserts acquired by pTZ18R from strains A19, AM, 15TP and TP28 could be excised by digestion with EcoRI and HindIII as 0.75 kb fragments; those from strains AM90 and AM108 were about 2.0 and 1.5 kb respectively. All sequences had the same set of minor differences from that of Lee et al., (1981): (i) the insertion of TA between nucleotides −88 and −87, (ii) the absence of AC (positions −62 and −61), and (iii) the substitution of T for C at positions 452 and 456. These changes are outside the sequences considered here and summarized in Fig. 5. The coding sequence of the promoter-proximal rpmB (protein L28) gene is preceded by a typical Shine–Dalgarno sequence (GGAG). There is a second potential ribosome-binding site 5' to the ATG codon that initiates translation of rpmG (protein L33).

The sequences from strains A19 and 15TP were the same. Strain TP28 had a single base change that altered the upstream Shine–Dalgarno sequence from GGAG to GGAA. This alteration was present in two separately amplified DNA preparations from each of two isolates of strain TP28 that had been maintained separately. Moreover, a spontaneous revertant of strain TP28 to faster growth had a single base change in the Shine–Dalgarno sequence back to that of strain 15TP.

The sequence from strain AM90 showed that the mobile element IS3 was inserted into rpmG. This accounts for the greater size of the operon. The insertion introduces an in-phase stop codon that should terminate translation of the protein after 25 (of the 54) amino acids have been polymerized. Insertion of IS3 was accompanied by the usual direct 3-nucleotide repeat in the coding sequence. In strain AM108, the element IS7 was inserted towards the distal end of rpmB, creating a direct 9-nucleotide repeat. Translation could give an N-terminal fragment of protein L28 with 49 of the 77 amino acids.

**Consequences of the genetic defects**

(a) Reduced translation from the altered Shine–Dalgarno sequence in strain TP28. lac fusions were made to compare the strengths of the Shine–Dalgarno sequences preceding rpmB in strains 15TP and TP28. The two leader sequences, amplified by PCR, were ligated into plasmid pUI533A and then transformed into strain RE74-807 (and some other revertants to antibiotic independence; Wild, 1988).
Fig. 5. Mutations in the rpmB,G operon. The sequence changes in strains TP28, AM108 and AM90 are shown. Potential Shine–Dalgarno sequences are underlined. Repeats created by insertion of IS1 and IS3 are overlined. The central approx. 400 nucleotides of IS3 were not sequenced.

JM109. A pair of transformants with leader sequences from strains 15TP and TP28 were grown in parallel overnight in minimal medium with tetracycline, then reinoculated and grown from OD450 0·05 to 0·50. Comparisons of β-galactosidase activities were made on two such separately isolated pairs. With the first, the activity from the plasmid with the 15TP leader was equal to 100; that with the TP28 leader was then 20. For the second pair of transformants, the activities were 90 and 20 respectively. These figures were reproducible (to within about 5%) in at least three separate comparisons of each pair. Thus the base change in the Shine–Dalgarno sequence of strain TP28 reduces translation of β-galactosidase by 75–80%.

(b) Synthesis of protein L28 by strain AM90. If protein L33 regulates translation of the rpmB,G operon, synthesis of protein L28 should be poorly controlled in strain AM90, which lacks protein L33. Strain AM90 labelled with [3H]lysine for two generations in TAA medium was mixed with strain A19 grown similarly with [14C]lysine. The ribosomal proteins were extracted and separated on two-dimensional gels. In four experiments, A_i values (see Methods) for protein L28 were 0·84, 0·95, 0·98 and 1·01. Thus protein L28 does not accumulate in strain AM90. Moreover, in pulse-labelling experiments with strain AM90 (similar to those below with strain AM108), protein L28 was synthesized at a normal rate and was then stable. The implication is that protein L33 by itself does not regulate the rpmB,G operon.

(c) Rates of synthesis of ribosomal proteins by strain AM108. In strain TP28 ribosomal protein synthesis is poorly balanced. At least ten proteins (S6, S12, S13, L5, L11, L14, L24, L27, L32, L34) are made at rates typically 20–30% faster than required to sustain ribosome synthesis; in all cases except protein L11, 'excess' protein is degraded (Butler & Wild, 1984). For similar experiments with strain AM108, organisms growing exponentially in TAA medium were pulse-labelled for 2 min with carrier-free [3H]lysine, then chased for 2 min with excess non-radioactive lysine. A sample was taken and
Effect of rpmB,G mutations on ribosome synthesis

Fig. 7. Stability of ribosomal proteins in strain AM108. The panels show $A_i$ values after a 2 min pulse with $[^3H]lysine$ and during a subsequent chase with excess lysine. (a, b, c) Proteins S2, S19, L17, representative of stable proteins; (d) protein S18 (see text); (e–l) the unstable proteins S13, S14, L5, L14, L15, L20, L24 and L27. The panels superimpose results of three separate experiments ($\bigcirc$, $\bullet$ and $\square$).

others at 20, 50 and 100 min; each was mixed with a culture of strain AM108 labelled with $[^14C]lysine$ during growth for two generations. Proteins were extracted from the mixtures for electrophoresis. The $A_i$ values from the 4 min sample indicate relative rates of synthesis; values in later samples show the subsequent stability of the newly-made proteins. The measurements encompassed about 45 proteins. Those excluded were L28 and L33, missing from strain AM108, and, for technical reasons, S1, S11, L7 L12, and L34. One experiment is summarized in Fig. 6. In the pulsed sample (Fig. 6a), about a quarter of the $A_i$ values are outside the range 0.85–1.14. Thus strain AM108 fails to make an appreciable proportion of its ribosomal proteins at an optimum rate, although, after the chase (Fig. 6b), $A_i$ values are tightly clustered and reflect the ribosomal protein content of exponentially-growing organisms. The $A_i$ values for some individual proteins are shown in Fig. 7. The largest category is the 30 or so made at normal rates and subsequently stable; three examples are S2, S19 and L17 (Fig. 7a–c). Protein S18 is exceptional; the $A_i$ value increases from 0.5 to 1 during the chase (Fig. 7d), probably because S18 is modified by an acetylation that alters its mobility (Isono, 1980). Seven ribosomal proteins are consistently oversynthesized ($A_i$ 1–2–1.45) and their excess degraded. These are S13, S14, L5, L14, L15, L20 and L27; L24 is a possible member of this group (Fig. 7e–l). Similar experiments (not shown) were done with strains AM and A19. Here, ribosomal protein synthesis was well balanced, with nearly all proteins made at normal rates and then stable. In both strains, the exceptions were (i) proteins S5 and S18, whose $A_i$ values increased during the chase from about 0.8 (S5) or 0.4 (S18) to 1.0 (like S18, protein S5 is acetylated; Isono, 1980), and (ii) proteins S6 and S19, which were moderately oversynthesized ($A_i$ 1.1–1.2) and somewhat unstable (in strain AM, protein L20 was also in this category, as was protein S21 of strain A19).
Discussion

Strain TP28 grows slowly, has a high RNA content, accumulates ribosome precursor particles, shows unbalanced synthesis of ribosomal proteins and has completed ribosomes that function poorly. This complex phenotype results from a G to A base change in a ribosome-binding site in the leader region of the mRNA of the rpmB,G operon. The change reduces the number of base pairs between the Shine–Dalgarno sequence and its complement in 16S rRNA from four to three. This is perhaps sufficient to reduce translation in lac fusions by the 80% noted. However, as emphasized for example by Gold (1988), sequence changes often affect secondary and tertiary structures that can determine accessibility of ribosome-binding sites and initiation codons. The 80% reduction in fusions is greater than the 50% reduction in synthesis of proteins L28 and L33 in strain TP28 (Butler & Wild, 1984). The latter figure may be an underestimate. However, if translation of the operon is inhibited by a product, the reduced production of L28 and L33 by strain TP28 may be partially compensated by less inhibition of translation.

Strains AM90 and 108 were isolated as revertants of strain AM to erythromycin-independence (Dabbs, 1979). Strain AM90 has the element IS3 inserted into rpmG while in strain AM108, IS1 is located within rpmB. At the ends of both insertions are the repeated sequences that distinguish newly-transferred elements from resident sequences such as the IS1 copy immediately distal to the gene (rpsT) for ribosomal protein S20 (Mackie, 1986). Such sequences are polar (Jaskunas & Nomura, 1977) so that insertion into rpmB should prevent synthesis from rpmG. Inactivation of a ribosomal protein gene by an insertion sequence has been noted in other circumstances (e.g. Schnier & Isono, 1984) but is not the only mechanism for suppressing erythromycin-dependence. In strain AM109, suppression results from an amber mutation in rplX, coding for protein L24 (Nishi et al., 1985), while electrophoretically-altered proteins, and therefore presumably missense mutations, produce reversion of the erythromycin-dependent strain 103 to independence (Wild, 1988).

In strain TP28, rates of synthesis of proteins L28 and L33 are reduced to similar extents; internal initiation of translation of protein L33 is thus unlikely. This operon therefore provides another example of translational coupling in ribosomal protein synthesis (Nomura et al., 1984). In most ribosomal protein operons, regulation of translation is by a protein of the operon that is preferentially incorporated into assembling ribosomes but if in excess, binds to an equivalent secondary or tertiary structure in its mRNA, thereby blocking translation (Draper, 1989). If regulation of the rpmB,G operon conforms to this pattern, the protein is unlikely to be L33 because synthesis of protein L28 is normal in strain AM90, which fails to make L33. [In strain AM90 there may be synthesis of an N-terminal fragment of protein L33. This is unlikely to be stable; no cross-reacting material was detected by Dabbs et al. (1983).]

The contrasting phenotypes of strains TP28 and AM108 are striking. The former undersynthesizes proteins L28 and L33, has a high RNA content and accumulates quantities of abnormal ribosome precursor particles. The latter synthesizes neither protein but makes ribosome virtually normally; moreover, the RNA content is no higher than that of its parent, strain AM, and about half that of strain 807, which has the ribosome mutation of strain TP28. Ribosome assembly by strain TP28 requires the maturation of 47S particles to 50S ribosomes. If the major limiting factor were the restricted availability of proteins L28 and L33, there should be a much greater delay in strain AM108. However, in strain AM108, both assembly and the assembly time are normal. It is thus likely that the kinetics of maturation of 47S particles involve not only the binding of proteins L28 and L33 but also the (re)association of the other proteins (L16, L25, L27) in which 47S particles are deficient (Butler & Wild, 1984). The substoichiometry of protein L16 (about 0.3 of a copy per particle) may be particularly significant. The 47S particles have no peptidyltransferase activity (Butler et al., 1980); protein L16 is implicated in assembly and stabilization of the peptidyltransferase centre (Tate et al., 1987). Reconstitution intermediates that lack protein L16 show large Mg\(^{2+}\)-dependent conformational changes (Dohme & Nierhaus, 1976), as do 47S particles. In some strains of E. coli that can overexpress mutant forms of protein L2, synthesis of 50S subunits is blocked at the stage of aberrant ‘48S’ particles that have no protein L16 and have reduced amounts of proteins L28, L33 and L34; results do not show whether the reductions are due to the alteration in L2 or the absence of L16 (Romero et al., 1990). In the in vitro assembly map for E. coli 50S ribosomes (Herold & Nierhaus, 1987), proteins L16, L25, L27, L28 and L33 cluster around protein L15. All, except protein L33, which is present in substoichiometric amounts in R100(1) particles, are in the second group of proteins to bind during assembly in vitro. Structural relationships between this group of proteins may help explain some of the features of ribosome assembly in strain TP28. However, it is still puzzling why these are not reflected in strain AM108.

Regulation of ribosomal protein synthesis is no more impaired in strain AM108 than in TP28. Strain TP28 oversynthesizes proteins S6, S12, S13, L5, L11, L14, L27, L32 and L34 (Butler & Wild, 1984); strain AM108 makes an excess of, and then degrades, S13, S14, L5,
L14, L15, L20, L24 and L27. The catalogues overlap and together comprise the first four products of the long spc operon (proteins L14, L24, L5 and S14) plus other proteins whose genes are promoter-proximal in their operons. (The exception is protein L15, whose gene is distal in the spc operon.) One explanation (Butler & Wild, 1984) for unbalanced synthesis in strain TP28 was that stresses in one regulatory circuit (rpmB,G) were reflected in other operons. In this case, failure of strain AM108 to make the two proteins should, but does not, have more dramatic consequences. Another, now more likely explanation, is that the ribosomes of both strains translate with difficulty and are prone to detach prematurely from mRNA. This polarity might lead to oversynthesis of proteins whose genes are promoter proximal.

It is also not clear why strain TP28 accumulates much more RNA than strain AM108. A contrasting situation is that with strains R1 and R8, two revertants to independence of the erythromycin-dependent strain, 103: the strain (R8) that lacks a protein (L19) has a high RNA content; the content is normal in the strain (R1) with an L19 of altered mobility (Wild, 1988). It is difficult to explain these, and other, examples as regulation by ribosomal proteins that are altered or absent. A more promising explanation is that accumulation of RNA results from failure of growth rate control by completed ribosomes. The proposal (Jinks-Robertson et al., 1983) that rRNA synthesis is inhibited by free, nonfunctioning ribosomes has been modified by the suggestion that ribosome production is monitored at initiation (or perhaps subsequent steps) of protein synthesis (Cole et al., 1987; Yamagishi et al., 1987). On this basis, the ribosomes of strain AM108 lack two proteins but retain their signalling capacity, whereas ribosomes of strain TP28, with a complete set of proteins but perhaps conformationally altered, are unable to signal properly. Clarification may come by comparing the ability of these ribosomes to function in the stages of protein synthesis. An alternative is to examine RNA synthesis by strains with established defects in protein synthesis such as the mutant lacking protein S20 that is defective in translation initiation (Gotz et al., 1990).

The early stages of this work benefited greatly from discussions with Dr Peter Butler, who died in 1991. We salute his memory and his courage.
