(Received 9 September 1992; revised 2 December 1992; accepted 15 December 1992)

The gene encoding cyclohexadienyl dehydratase from *Pseudomonas aeruginosa*, designated *pheC*, was cloned in *Escherichia coli* and sequenced recently by Zhao et al. (*Journal of Biological Chemistry* 267, 2487–2493, 1992). N-Terminal sequencing of the purified cyclohexadienyl dehydratase yielded a run of 11 residues which matched perfectly with the deduced amino acid residues 26–36. This showed that a 25 residue peptide was cleaved from the N-terminus of a preprotein formed in *E. coli*. The amino acid composition of the 25 residue peptide was typical of signal sequences for periplasmic proteins. Most or all of the cyclohexadienyl dehydratase was released from *P. aeruginosa* and *E. coli* carrying the *pheC* gene following spheroplast formation, osmotic shock or chloroform treatment. The location of the enzyme in the periplasm of both *E. coli* and *P. aeruginosa* was confirmed by Western blotting analysis using antibody prepared against PheC. Electron microscopy using immunogold labelling showed an apparent localization of cyclohexadienyl dehydratase at the polar regions of the periplasmic space in *E. coli*.

**Introduction**

Cyclohexadienyl dehydratase catalyses two analogous aromatization reactions: either the conversion of prephenate to phenylpyruvate or the conversion of L-arogenate to L-phenylalanine (Jensen & Fischer, 1987). The enzyme was first described in *Pseudomonas aeruginosa*, an organism which possesses it as a component of one of the two separate pathways for L-phenylalanine biosynthesis (Patel et al., 1977). The *P. aeruginosa* gene encoding cyclohexadienyl dehydratase, denoted *pheC*, has been cloned and sequenced recently, and the product expressed in *Escherichia coli* purified to electrophoretic homogeneity (Zhao et al., 1992). Kinetic studies indicate that this enzyme probably possesses a single substrate-binding site which can utilize either prephenate or L-arogenate.

Although cyclohexadienyl dehydratase is widely distributed among Gram-negative prokaryotes (Ahmad et al., 1990), its physiological role is unclear. Molecular genetic techniques have facilitated the production of *P. aeruginosa* PheC in large quantities by use of a recombinant *E. coli* strain (Zhao et al., 1992). Comparison of its N-terminal amino acid sequence with that deduced from the nucleotide sequence led to the unexpected finding that this protein is derived from a precursor with a cleavable leader sequence, and that the protein is localized in the periplasmic space of *P. aeruginosa*. Thus, cyclohexadienyl dehydratase is spatially separated from its prephenate dehydratase counterpart in the cytoplasm, which is dedicated to the classic phenylpyruvate pathway (Davis, 1953) of L-phenylalanine biosynthesis. This indicates that cyclohexadienyl dehydratase is involved in some unknown function in the periplasm.

**Methods**

**Bacterial strains, plasmids and media.** Bacterial strains and plasmids used in this study are listed in Table 1. LB and M9 (Maniatis et al., 1982) were used as enriched and minimal media, respectively. For induction of alkaline phosphatase activity in *P. aeruginosa*, the organic phosphate medium of Cheng et al. (1970) was used. Ampicillin (50 μg ml⁻¹), L-tyrosine (50 μg ml⁻¹) and thiamin (17 μg ml⁻¹) were added when appropriate.

**Biochemicals.** Restriction enzymes and T4 DNA ligase were obtained from BRL. Prephenate and L-arogenate were prepared from *Salmonella typhimurium tyrA9* (Nishioka et al., 1967) by the procedures of Bonner et al. (1990). Sephadex G-200, DEAE-cellulose and hydroxylapatite were obtained from Sigma, Whatman and Bio-Rad, respectively. *M*₅₀ standards for SDS-PAGE (α-lactalbumin, *M*₅₀ 14400; soybean trypsin inhibitor, 20100; carbonic anhydrase, 30000; ovalbumin, 43000; bovine serum albumin, 67000; and phosphorylase b, 94000) were purchased from Bio-Rad.
Expression construct of *P. stutzeri* *pheA*. The intact *pheA* gene encoding the bifunctional P-protein (chorismate mutase/prephenate dehydratase) from *P. stutzeri* (Fischer *et al.*, 1991) was cloned from pJF1954 into pUC19 at the *SphI*-PstI restriction sites, and the resulting construct, designated pJZpp, was found to overexpress the P-protein in *E. coli*.

Purification of *PheC*. The cloned *pheC* gene product expressed in *E. coli* was purified as described previously (Zhao *et al.*, 1992). The cyclohexadienyl dehydratase isolated directly from *P. aeruginosa* was purified in five steps as described previously (Zhao *et al.*, 1992) with the following modifications. Ammonium sulphate precipitation was omitted. After the third step (Sephadex G-200 gel-filtration), the fractions possessing cyclohexadienyl dehydratase activity were pooled and applied to a hydroxylapatite column (1.5 x 30 cm) as described previously (Zhao *et al.*, 1992). A sample (2.205 g) of crude extract from *P. aeruginosa*, possessing an initial specific activity of 3.71 nmol min^{-1} (mg protein)^{-1} when cyclohexadienyl dehydratase was assayed as aroenate dehydratase, was purified 1298-fold.

N-Terminal amino acid sequencing. The N-terminal sequences of the purified proteins were determined by using an Applied Biosystems 470A Protein Sequencer with on-line 120A PTH-Analyzer at the Protein Core Facility of the University of Florida.

*M* determinations. Native *M* values of the purified proteins were estimated by gel-filtration, and subunit *M* values were determined by SDS-PAGE (Laemmli, 1970).

Antibody preparation and Western blotting analysis. *P. aeruginosa* cyclohexadienyl dehydratase purified from *E. coli* (0.6 mg) was injected every 7 d into a New Zealand White rabbit (Hiebert *et al.*, 1984), and antiserum was collected 1 week after a third injection. The Western blot procedure was done as described by Towbin *et al.* (1979).

Isolation of periplasmic fractions from *E. coli*. *E. coli* JPE2255 carrying plasmid pJZlg (Table 2) or pJZpp (Table 3) was grown in 1.2 litres of either LB medium supplemented with ampicillin, or M9 medium (data not shown) supplemented with ampicillin, L-tyrosine and thiamin. The cells were harvested by centrifugation during the late exponential phase of growth. Each culture was divided into four 300 ml parts. The cell pellet obtained from one part of the culture (1.13 g wet weight) was subjected to osmotic shock (Neu & Heppel, 1965). After centrifugation, the supernatant fluid was collected and referred to as the periplasmic fraction. The cell pellet remaining after osmotic shock was sonicated. The sonicated preparation was centrifuged at 150000 g for 60 min. The supernatant fraction was collected and then passed through a PD-10 Sephadex column. This preparation was designated the cytoplasmic fraction. A second part of the culture was used to obtain periplasmic and cytoplasmic fractions from spheroplast preparations (Birdsell & Cota-Robles, 1967). Chloroform treatment was carried out as described by Ames *et al.* (1984). The fourth part of the culture was sonicated, centrifuged and desalted as described above, but omitting the osmotic shock step. This preparation is referred to as the unfraccionated extract.

Isolation of periplasmic fractions from *P. aeruginosa*. *P. aeruginosa* strains were grown in 800 ml of organic phosphate medium and harvested during the late exponential phase of growth. The cultures were divided equally into two 400 ml parts (1.5 g wet weight). One part of the culture was treated with chloroform (Ames *et al.*, 1984), and the supernatant fluid recovered was designated the periplasmic fraction. The second part of the culture, which was not treated with chloroform, was sonicated, centrifuged and desalted as described above to yield the unfraccionated extract.

Enzyme assay and protein determination. Prephenate dehydratase was assayed as described by Cotton & Gibson (1965). Aroenate dehydratase was assayed by measuring the formation of L-phenylalanine using HPLC (Fischer & Jensen, 1987). Alkaline phosphatase was assayed as detailed by Brickman & Beckwith (1975). Protein was measured using the procedure of Bradford (1976).

Electron microscopy. Exponential-phase populations of *E. coli* JPE2255(pJZlg) were fixed by use of 2.5% formaldehyde/0.5% glutaraldehyde and then embedded in Lowicryl K4M. After incubation with either antibody or pre-immune serum and gold-particle labelling, the thin sections were photographed under a JEOL 100-CX electron microscope.

Fig. 1. SDS-PAGE analysis of the cloned P. aeruginosa pheC gene product purified from E. coli and the cyclohexadienyl dehydratase purified directly from P. aeruginosa. The samples were run on a 15% polyacrylamide gel. Lane 1, M, standards; lanes 2 and 4, cyclohexadienyl dehydratase purified from P. aeruginosa PAO1; lane 3, cyclohexadienyl dehydratase purified from E. coli.

Results

N-Terminal amino acid sequencing of purified cyclohexadienyl dehydratase

Purification of the cloned PheC was done as described previously (Zhao et al., 1992). After the gel-filtration step, a single protein band was resolved by SDS-PAGE. The subunit Mr was 28,000 (Fig. 1), in contrast to a value of 29,500 reported earlier (Zhao et al., 1992). The native Mr of the purified pheC product was estimated by gel-filtration to be 72,000.

The N-terminal sequence of the purified pheC gene product was determined to be Gln-Glu-Ser-Arg-Leu-Asp-Arg-Ile-Leu-Glu-Ser. This sequence matched perfectly with the amino acids deduced at positions 26 to 36 (Zhao et al., 1992). This indicated that an amino-terminal peptide (25 residues in length), a possible signal sequence, was cleaved in E. coli (Fig. 2).

In order to eliminate the possibility that this cleavage might be an artifact of cloning in E. coli, the cyclohexadienyl dehydratase was also purified directly from P. aeruginosa. The activities of prephenate dehydratase and arogenate dehydratase co-eluted, and the ratio of the two activities was constant throughout the purification process. After the five steps of purification used, the enzyme was homogeneous as judged by SDS-PAGE. The subunit Mr of 28,000 (Fig. 1) was identical to that of the cloned pheC gene product. The native Mr of the purified enzyme was determined to be 72,000 by gel-filtration.

The cyclohexadienyl dehydratase purified directly from P. aeruginosa was sequenced at the amino-terminus. The 11 amino acid residues sequenced were identical to those determined for the cloned pheC gene product purified from E. coli. The matching sequence corresponded to the deduced sequence spanning residues 26 to 36, thus showing that cleavage of the amino-terminal peptide also occurred in P. aeruginosa.

The amino-terminal peptide of the cyclohexadienyl dehydratase from P. aeruginosa shown in Fig. 2 exhibits features typical of known signal sequences for periplasmic proteins (Oliver, 1986). Thus, the P. aeruginosa amino-terminal peptide possesses a basic amino terminus (Lys, Arg and His), a hydrophobic core region, and a processing-site motif (Leu-Gln-Ala). The length of this amino-terminal peptide also falls within the range for periplasmic signal sequences (Oliver, 1986).

Spheroplast preparation, osmotic shock and chloroform treatment

The evidence for N-terminal processing suggested that the mature cyclohexadienyl dehydratase might be located in the periplasm. The results obtained following application of different techniques for releasing peri-

plasmic proteins from *E. coli* strains carrying pJZlg and pJZpp are summarized in Tables 2 and 3. The known periplasmic protein, alkaline phosphatase, was monitored as a positive control. The efficiency of different techniques for release of cyclohexadienyl dehydratase (Table 2) was in the order: osmotic shock (91%), chloroform treatment (86%), and spheroplast preparation (81%).

Parallel studies were carried out with the JP2255(pJZpp) construct, because in this strain the *pheA* gene of *P. stutzeri* is highly expressed, but the gene product is a cytoplasmic protein. Thus, it served as a negative control in this study. In marked contrast to results obtained with alkaline phosphatase, less than 1% of the prephenate dehydratase activity was found in the periplasmic fractions when *E. coli* JP2255(pJZpp) was subjected to spheroplast preparation, osmotic shock or chloroform treatment.

Results similar to those given in Tables 2 and 3 were obtained when *E. coli* JP2255 carrying pJZlg or pJZpp was grown in M9 minimal medium, except that alkaline phosphatase activities were repressed to very low levels by the phosphate content of the medium.

The results of chloroform treatment of *P. aeruginosa* PAO1 are given in Table 4. The fact that the cyclohexadienyl dehydratase rather than the *pheA*-encoded prephenate dehydratase was present in the periplasmic compartment of *P. aeruginosa* PAO1.
Cyclohexadienyl dehydratase is periplasmic

Fig. 3. Immunocytological localization of cyclohexadienyl dehydratase. (a) Exponential-phase cells of \textit{E. coli} JP2255(pJZ1g) were prepared as described under Methods. Thin sections of these cells were incubated with antibody prepared against purified PheC, labelled with gold particles, and examined under the electron microscope. Cyclohexadienyl dehydratase molecules are visualized as black dots in the thin sections shown. Arrowheads indicate accumulation of gold particles in the polar region of the periplasm. (b) Control cells were treated with pre-immune serum instead of specific antibody and then handled as described in (a). Bars, 0.1 \( \mu \text{m} \).

fractions was established by its insensitivity to feedback inhibition by L-phenylalanine and by its ability to utilize L-aroogenate as substrate, both of which are characteristics of the cyclohexadienyl dehydratase but not of the bifunctional P-protein (Patel \textit{et al.}, 1977; Xia \textit{et al.}, 1991; Zhao \textit{et al.}, 1992).

Since cells of \textit{P. aeruginosa} undergo massive lysis during the osmotic shock process due to their sensitivity to EDTA (Wilkinson, 1967), this procedure could not be used. The chloroform treatment method resulted in the release of 90\% of the activity from the periplasmic space of \textit{P. aeruginosa} PAO1, but only 56\% from another commonly used strain, PAT2. This strain difference is not specific for cyclohexadienyl dehydratase, as shown by the parallel results obtained with alkaline phosphatase.

We confirmed the results of Cheng \textit{et al.} (1970), who found that simple washing in 0.2 M-Mg\(^{2+}\) effectively releases 100\% of the PAO1 alkaline phosphatase activity. Interestingly, this treatment was completely ineffective for release of periplasmic cyclohexadienyl dehydratase.

Mutant PAOH636 is deficient in porin protein F and leaks periplasmic proteins into the growth medium (Woodruff & Hancock, 1988). Table 4 shows that over 20\% of both alkaline phosphatase and cyclohexadienyl dehydratase were lost into the growth medium. Under comparable growth conditions neither of the periplasmic enzyme activities were found in the culture media of strains PAO1 or PAT2. The data given in Tables 2 to 4 are representative of results obtained from at least three and as many as five repetitions of experiments. The values obtained in different experiments were within 10\% of one another.

\textit{Western blotting analysis of the cyclohexadienyl dehydratase in the periplasmic fractions}

Periplasmic fractions collected following osmotic shock in \textit{E. coli} or chloroform treatment of \textit{P. aeruginosa} PAO1 were first concentrated using a PM-10 membrane and then subjected to SDS-PAGE. The proteins were then transferred to a nitrocellulose membrane and probed with antibody prepared against the purified \textit{pheC} product. One control lane was also probed with pre-immune serum. Cyclohexadienyl dehydratase was readily detected in the periplasmic fractions of \textit{E. coli} JP2255(pJZ1g) and \textit{P. aeruginosa} PAO1 (data not shown). Antibody prepared against the \textit{pheC} product did not cross-react with the bifunctional P-protein.
Immunogold labelling

Incubation of ultra-thin sections of *E. coli* JP2255(pJZ1g) with gold-labelled antibody resulted in the electron microscopic visualization of the subcellular localization shown in Fig. 3. The majority of the antibody, as judged by the location of gold particles on the section, bound to the polar regions of the periplasm. Little or no antibody was bound to the remaining periplasmic regions, or to the cytoplasmic space. Control preparations were practically devoid of label.

A comparable experiment with *P. aeruginosa* PAO1 did not result in visualization of the cyclohexadienyl dehydratase location, presumably due to the low quantities of the enzyme.

Discussion

The periplasmic location of cyclohexadienyl dehydratase in *P. aeruginosa* has been established. Although cyclohexadienyl dehydratase has variable properties [e.g. *Erwinia herbicola* cyclohexadienyl dehydratase is a homo-tetramer made up of $M_r$ 18,000 subunits (Xia *et al.*, 1991)], while *P. aeruginosa* cyclohexadienyl dehydratase is a dimer of $M_r$ 28,000 subunits (Zhao *et al.*, 1992), cyclohexadienyl dehydratase from *E. herbicola* and other Gram-negative bacteria can be released from the periplasmic space by osmotic shock (unpublished data).

Cyclohexadienyl dehydratase is an enzyme component of one of two separate pathways for phenylalanine biosynthesis, an arrangement which is common in Gram-negative bacteria (Byng *et al.*, 1982). Its insensitivity to feedback inhibition is the basis for reference to this pathway as an ‘overflow’ pathway of phenylalanine biosynthesis in *P. aeruginosa* (Fiske *et al.*, 1983). This overflow pathway is not thought to function for primary phenylalanine biosynthesis in wild-type cells under most physiological conditions, where intracellular prephenate is maintained at low levels. However, it can partially suppress a *pheA* defect of the primary biosynthetic pathway, resulting in leaky growth (Berry *et al.*, 1987). When the major point of early-pathway control is eliminated in a 3-deoxy-D-arabino-heptulosonate-7-phosphate synthase-tyr mutant (in which allosteric control has been abolished), the unregulated cyclohexadienyl dehydratase permits an unrestrained flow of excess precursor molecules to L-phenylalanine. In view of the periplasmic location of cyclohexadienyl dehydratase, it appears that in the foregoing situations a fractional amount of an aromatic-pathway intermediate (such as prephenate or L-arogenate) must be diverted to the periplasm. In the case of the *pheA* leaky auxotroph, the phenylpyruvate or L-phenylalanine product must be transported back to the cytoplasm. A monofunctional species of chorismate mutase denoted CM-F (Xia & Jensen, 1992) exhibits a similar phylogenetic distribution as does cyclohexadienyl dehydratase (Ahmad & Jensen, 1988), and CM-F might also prove to be a periplasmic enzyme. If so, the point of pathway diversion with respect to compartmentation would be at the level of chorismate.

The location of cyclohexadienyl dehydratase in the periplasm with various scavenging enzymes suggests an interactive role with the immediate environment of the cell. One possibility relates to the ability of cyclohexadienyl dehydratase to convert L-arogenate to L-phenylalanine. Since higher plants use L-arogenate as an exclusive precursor of L-phenylalanine (Jung *et al.*, 1986), the diversion of plant L-arogenate to the microbial pool of L-phenylalanine would undermine the precursor resources of plant phenylalanine needed for phytoalexin synthesis. Because non-pathogenic relatives of plant pathogenic bacteria (e.g. *P. aeruginosa*) often possess cyclohexadienyl dehydratase, this ability to undermine the formation of plant defence compounds may also exist in saprophytic or opportunistic species of bacteria associated with plants. In this context, it is interesting that cyclohexadienyl dehydratase is absent in genera such as *Escherichia*, *Shigella*, *Salmonella* and *Proteus*, but is present in genera such as *Klebsiella*, *Erwinia* and *Serratia*. Species in the latter genera are known to associate with plant surfaces in a pathogenic or opportunistic mode. The ability to scavenge L-arogenate as an immediate precursor of L-phenylalanine may confer a metabolic advantage upon the bacterium since biosynthesis of aromatic amino acids is extremely expensive in energetic terms.

Alternatively, cyclohexadienyl dehydratase could be one component of a periplasm-localized arm of biosynthesis which is dedicated to the provision of phenylalanine to the periplasmic compartment for some as yet unidentified function. Such alternative roles of cyclohexadienyl dehydratase are not mutually exclusive. Inactivation of the *pheC* gene by molecular genetic techniques may illuminate the role(s) of cyclohexadienyl dehydratase in vivo.

Periplasmic proteins undoubtedly exhibit different localizations within the periplasmic compartment (Oliver, 1986). *P. aeruginosa* alkaline phosphatase has been suggested to be linked to the exocytosomal region through divalent Mg$^{2+}$ bridges (Cheng *et al.*, 1970). Results obtained with Mg$^{2+}$ washing show that *P. aeruginosa* cyclohexadienyl dehydratase does not share this feature, an indication that the spatial organization of the two enzymes is different. The apparent restriction of cyclohexadienyl dehydratase to the polar regions of the periplasm may be an important clue to the function of
this enzyme. Experiments to confirm this spatial location and to determine the mechanism accomplishing it are in progress.

This work was supported by grant DK38309 from the US Public Health Service. Robert E. W. Hancock generously provided the porin-deficient mutant PA0H636. This paper is Florida Agricultural Station Journal Series no. R-02681.
