A morphological characterization of *Borrelia anserina*

Kari Hovind-Hougen†

The morphology and ultrastructure of two strains of *Borrelia anserina* were investigated by electron microscopy of negatively stained and ultrathin sectioned cells. One was a cultivable strain originally isolated in the USA and the other was originally isolated in Nigeria and maintained in chickens. The cells were regularly helical, 9–21 μm long and 0.22–0.26 μm wide with a helix wavelength of about 1.7 μm. The cells were surrounded by a surface layer and appeared to divide by binary fission. The structure of the cells from each of the two strains was identical except that those of the USA strain possessed seven flagella inserted at each end and those from the Nigerian strain had eight.

**Keywords:** *Borrelia anserina*, morphology, ultrastructure, spirochaetes

**INTRODUCTION**

*Borrelia* species are known to be the causative agents of several human and animal diseases, for example relapsing fever, but relatively few studies were carried out on members of the genus until 1982 when *Borrelia burgdorferi* was found to be the causative agent of Lyme disease (Burgdorfer et al., 1982).

The study of *Borrelia* species has been hampered by the fact that only a few of them can be cultivated *in vitro* (Kelly, 1984). The type species, *Borrelia anserina*, has for example traditionally been maintained in embryonated chicken eggs or by serial passage in young domestic chickens. In 1986, however, it was found that it could be cultivated in Barbour–Stoenner–Kelly (BSK) medium (Anderson et al., 1986; Barboux et al., 1986) and thus made more easily available for further investigations.

Several reports have recently described serological and immunological differences between various isolates of *B. anserina* (Felsenfeld, 1971; DaMassa & Adler, 1979; Soni & Joshi, 1980). The aim of the present work was to determine whether such differences were reflected in the morphology and ultrastructure of the organisms. Consequently, it was decided to investigate two isolates of *B. anserina* which had not previously been studied in detail. For this purpose, a cultivable strain and a strain passaged in chickens were chosen. Finally, the ultrastructure of *B. anserina* was compared with previously published data on the morphology of several other *Borrelia* species, including *B. burgdorferi*.

**METHODS**

A subculture of *B. anserina* strain Es ATCC 49835 originally isolated by DaMassa & Adler (1979) was obtained from Professor R. C. Johnson, University of Minnesota, Minneapolis, USA. The strain was maintained by culture in BSK medium (Barboux et al., 1986) at 32 °C.

Blood from chickens infected with *B. anserina* in the northern region of Nigeria between 1966 and 1969 (Wouda et al., 1975; Leeflang & Ilemobade, 1977) was obtained from Dr F. Jongejan, University of Utrecht, The Netherlands. The blood had been stored in liquid nitrogen for over 20 years (F. Jongejan, personal communication). Four chickens, about 6–8 weeks old, were inoculated intramuscularly with approximately 0.02 ml of this blood. Blood samples from the chickens were examined daily by dark-field microscopy and the chickens were bleed on day 4, at which time there were too many organisms to count in each field at ×400 magnification. The blood was left to clot at +4 °C overnight and the serum containing the spirochaetes was pipetted off.

**Procedure for negative staining.** One to two-week-old cultures and sera from infected chickens were centrifuged at 9000 g for 20 min. The resulting pellets were resuspended to a suitable density in SMC (0.03%, w/v, sucrose in distilled water to which was added 0.01 M MgCl₂ and 0.01 M CaCl₂). Some cells were treated on the grids with 1% (w/v) sodium deoxycholate in water for 15 or 60 s. Negatively stained samples were prepared by the multiple drop technique (Hovind-Hougen & Birch-Andersen, 1971) from the suspension or directly from the sera. Ammonium molybdate (1%, w/v) in distilled water brought to pH 7 with NH₄OH was used for negative staining.

**Procedure for ultrathin sectioning of cells from cultures.** Cultures were centrifuged at 9000 g for 20 min. Cell pellets were prefixed in 1:5% (v/v) glutaraldehyde in 0.1 M cacodylate buffer, pH 7.2. After fixation and centrifugation the cells were gently mixed with melted 1:5% (w/v) Noble Agar (Difco) at 45 °C in the same buffer and small blocks with visible clusters of

RESULTS

Cells of both strains of B. anserina were found to be regularly waved spirochaetes, 8.9–21.2 µm long and with a wavelength of about 1.7 µm (Table 1, Fig. 1a). The cells had tapered ends. The full width of 0.22–0.26 µm was reached after 1–1.5 wavelengths from the ends. At high magnification, the cells from infected chicken blood were seen to possess eight flagella inserted at each end (Fig. 1b) whereas the cultivated cells possessed seven flagella inserted at each end (Fig. 1c). The cells appeared to be surrounded by a surface layer — here named the S-layer (Fig. 1c). Some micrographs showed, at the tip of the cells, a substructure of fine striations transverse to the cell (not shown). The cells appeared to divide by binary fission. Occasionally, dividing cells were seen in which the truncated ends of the two daughter cells were separated by their individual cytoplasmic membranes but still connected by the mutual outer membrane and S-layer (not shown). In these cells the insertion points of new flagella were present on either side of the division site. These observations are similar to those made on other spirochaetes.

Some cells were accidently damaged during preparation for electron microscopy. From these cells, and those treated with 1% sodium deoxycholate, the flagella were released from their insertions on the cytoplasmic bodies of the cells. The flagellar filament was seen to be sheathed (Fig. 1d), with an overall diameter of 19 nm and a core of 14 nm diameter. Thin, rather straight fibrils with a diameter of 4 nm were observed surrounding remnants of the cells treated with sodium deoxycholate (Fig. 1e). The basal complex of the flagellum was not completely freed from the cytoplasmic body of the cells after treatment with deoxycholate but was similar in structure to that seen previously (Hovind-Hougen, 1974; Soni & Joshi, 1980), i.e. each complex consisted of two narrow discs connected to a hook by a narrow neck (Fig. 1f).

Cross-sectioned cells showed the flagella between the outer membrane and the cytoplasmic membrane (Figs 1g, h). The flagella from each end overlapped in two separate bundles and did not appear to be interdigitated (Fig. 1g). The cytoplasm of the cells was densely packed with ribosomes and some mesosome-like structures were occasionally present.

Cytoplasmatic tubules of the type found in treponemal cells (Hovind-Hougen, 1976) were never observed in Borrelia cells during the present work.

DISCUSSION

The ultrastructure of the cells of the two strains examined in this study differed only in the number of flagella inserted at each end of the cells. The differences observed in wavelengths and widths of the organisms were considered to be of no significance. Differences in the number of flagella have previously been found for cells of B. burgdorferi isolates obtained from human patients. The cells isolated from patients in the USA had seven flagella inserted at each end whereas those isolated from Swedish patients had eight, and showed some serological differences in reaction when tested with monoclonal
Morphology of *Borrelia anserina*

Fig. 1. Electron micrographs of *B. anserina*. (a)–(f) Cells negatively stained with 1% ammonium molybdate. (a) Regularly waved cell of a cultivable strain. (b) End of a cell of a strain isolated from chicken blood. The organism has eight flagella inserted at the end of the cell. The flagella are best counted in the region marked with the letter F. (c) End of a cell of a strain cultivated in BSK medium. The organism has seven flagella inserted at the end of the cell. The flagella are best counted in the region marked with the letter F. Note the triple layered borderline of the cell envelope (arrows). (d), (e), (f) Parts of cells of a strain cultivated in BSK medium and treated on the specimen grids with 1% sodium deoxycholate for 1 min. (d, f) or 15 s (e). Some of the flagella (F) are still attached to the cellular debris. The basal complexes on some of the flagella can be seen to consist of two discs (D) connected to a hook (H) by a narrow neck (N). Part of an unsheathed flagellar shaft is present in (d) (arrowhead) and thin, rather straight fibrils are seen between the flagella in (e) (arrows). (g), (h) Ultrathin sectioned cells of cultivable (g) and the non-cultivated (h) strains of *B. anserina*. The flagella (F) are situated between the outer membrane (O) and the cytoplasmic membrane (C) of the cells. Note that the two bundles of flagella in the cross-sectioned cells do not interdigitate. The cytoplasm of the cells is densely packed with ribosomes (R). Bars: (a), 5 μm; (b)–(h), 100 nm.

Antibodies (Hovind-Hougen et al., 1986). Other spirochaetes, such as the cultivable treponemes, which show differences in numbers of flagella also show serological and antigenic differences to the extent that they are assigned to different species (Fiehn, 1989).

Distinct serological and immunological properties of different isolates of *B. anserina* are shown by lack of cross-protection against cells of heterologous isolates, and by the inability of sera from infected chickens to immobilize borrelia from heterologous isolates (DaMassa & Adler,

1979; Soni & Joshi, 1980). The ultrastructure of these isolates has apparently not been examined. Conversely, no attempt was made to investigate the immunological and serological properties of the isolates studied in the present work.

Cells of *B. anserina* differ from those of *B. burgdorferi* by having a shorter wavelength (Tables 1 and 2).

The outer membrane of *B. anserina* is covered by a surface layer with a substructure of fine striations. Such striations are also seen on cells from European isolates of *B. burgdorferi* whereas no substructure and no S-layer are seen on cells from American isolates (Hovind-Hougen et al., 1986). The morphology of cells of *B. anserina* also differs from that of previously examined cells of *B. recurentis* and some borrelia strains isolated in Iran and Africa (Hovind-Hougen, 1974; Karimi et al., 1979). The *B. anserina* cells are thinner and less pointed in shape and contain fewer flagella, which are sheathed in contrast to those of the *B. recurentis* group which possess unsheathed flagellar shafts (Table 2).

In recent studies on the antigenic relatedness of *B. anserina* and *B. burgdorferi* only one strain of *B. anserina* was used (Walker et al., 1989). This was also the case in a study on attenuation of *B. anserina* by serial passage in liquid medium (Levine et al., 1990). Further comparative studies on the morphology, metabolism, and antigenic and genetic characters of different *B. anserina* strains are needed before the necessary criteria for a full description of the type species of the genus *Borrelia* can be given.

**ACKNOWLEDGEMENTS**

I am indebted to Dr R. M. Dwars, University of Utrecht, The Netherlands, for establishing my contact with Dr F. Jongejan, Institute of Infectious Diseases, Faculty of Veterinary Medicine, also at the University of Utrecht. Dr Jongejan kindly provided me with the Nigerian strain of *B. anserina*. I am also indebted to Professor R. C. Johnson, Department of Microbiology, University of Minnesota, Minneapolis, USA, for providing me with the cultivable strain of *B. anserina*. In addition, I am grateful to Dr B. Brest Nielsen for helping me with the infection of the chickens, and to Dr A. Birch-Andersen for his advice and help with the preparation of the manuscript. Finally, I wish to thank L. Jakobsen for sectioning and electron microscopy, E. Müller and
Morphology of *Borrelia anserina*

for the photographic work and K. Moeller for secretarial assistance.
