The oesophageal epithelium appears to be one of the primary cell targets of *Candida albicans* in AIDS patients. To study this interaction, we have established an *in vitro* adherence assay using a human epithelial oesophageal cell line (HET1-A). When yeast cells were grown in 500 mM D-galactose, adherence increased significantly over cultures prepared in 500 mM D-glucose. In addition to HET1-A cells, adherence of the organism grown in D-galactose to human buccal epithelial cells and a murine alveolar macrophage cell line was also higher. Adherence of yeast cells to HET1-A cells was partially inhibited in the presence of D-glucosamine or N-acetyl-D-glucosamine, but not with D-mannose, D-glucose, L-fucose or D-galactose. Attachment to HET1-A cells was studied using scanning and transmission electron microscopy. Partial phagocytosis of adhering yeast cells was observed occasionally within the first 90 min following infection, as evidenced by the formation of HET1-A pseudopodia in instances of close contact with yeast cells. The influence of D-galactose on cell surface proteins was studied by analysing β-mercaptoethanol-extracted proteins from yeast cells grown in either 500 mM D-galactose or D-glucose. From D-galactose-grown cells only, a glycoprotein of approximately 190 kDa was observed in Aurodye-stained SDS-PAGE gels and in Western blots using an immunoglobulin fraction (IgG) prepared from sera of rabbits infected with the organism. These studies demonstrate that *C. albicans* adheres to human oesophageal cells and may utilize cell surface proteins whose synthesis is nutritionally regulated.

**INTRODUCTION**

Adherence of *Candida albicans* to mammalian cells appears to be essential for the establishment of an infection by the organism (Calderone & Braun, 1991; Cutler, 1991; Calderone & Wadsworth, 1993). There is considerable evidence that cell surface glycoproteins of the organism recognize both the extracellular matrix proteins of endothelial cells as well as epithelial fucosyl- or glucosamine-containing glycosides or glycosphingolipids (Critchley & Douglas, 1987a; Tosh & Douglas, 1992; Yu *et al.*, 1994). Thus, it would appear that *C. albicans* is able to recognize a variety of host cell receptors through the use of an as yet unknown number of cell surface adhesins. This observation is not surprising when one considers the variety of host cells and tissues which can be colonized and invaded by the organism.

The AIDS epidemic has resulted in an increased number of patients with oral, vaginal and oesophageal candidiasis (Georgopapadakou & Walsh, 1994; Klein *et al.*, 1984), yet little is known about the recognition of oesophageal epithelial cells by *C. albicans*. We have initiated studies of this nature using an SV-40-transformed human oesophageal cell line (HET1-A) established by Stoner *et al.* (1991). When transformed, these cells are not tumourigenic and retain an epithelial cell morphology and the typical array of epithelial cell surface antigens.

McCourtie & Douglas (1981) observed that when yeast cells were incubated in 500 mM D-galactose, adherence of the organism to human buccal epithelial cells (HBEC) was significantly increased compared to yeast cells from...
cultures grown in equimolar concentrations of D-glucose. Additionally, they reported that the cell surface of galactose-grown yeast cells appeared fibrillar, and the yield of adhesin from culture supernatants was greater (McCourtie & Douglas, 1984). In this report, we have investigated the influence of carbon sources on the adherence of C. albicans to HET1-A cells and a murine alveolar macrophage cell line (MH-S) in addition to HBEC. The attachment of yeast cells to HET1-A cells was also studied by electron microscopy. Finally, we investigated the influence of carbon sources on the adherence of yeast cells to HET1-A cells grown in equimolar concentrations of D-glucose. The attachment of yeast cells to HBEC. The adherence of yeast cells to HET1-A cells was also measured in the presence of the filter were transferred to microscope slides and stained with crystal violet to determine the percentage adherence. Adherence was expressed as the percentage of HBEC with adhering yeast cells. The MH-S (murine alveolar macrophage) adherence assay was performed using monolayers on glass coverslips as described above. MH-S cells were infected with approximately 1 x 10^5 yeast cells per coverslip. After a 90 min incubation at 37 °C, the coverslips were washed with HBSS and stained with the Gram stain. The percentage of MH-S cells with adhering yeast cells was determined as described above for the HET1-A cell adherence assays. All adherence assays were performed at 37 °C in an atmosphere of 5% CO2. Adherence to HET1-A cells was also measured in the presence of the following sugars: D-galactose, D-glucose, L-fucose, N-acetyl-D-glucosamine, D-mannose and D-glucosamine, each at concentrations of 50–200 mM. Adherence was measured after a 90 min incubation as described above.

**Scanning electron microscopy.** Monolayers of HET1-A cells (5 x 10^5 cells per well) were prepared on 12 mm glass coverslips in tissue culture dishes (40 mm; Nunc, VWR Scientific). The monolayers were infected as described above and after a 90 min incubation at 37 °C the coverslips were removed, washed three times with PBS (pH 7.4), fixed in 1% (v/v) paraformaldehyde/3% (v/v) glutaraldehyde for 20 min, washed with PBS and post-fixed with 1% (v/v) osmium tetroxide in PBS. Subsequently, the infected monolayers were washed with PBS, dehydrated with a graded series of acetones and subjected to critical point drying (Sanidri-780). The samples were then coated with platinum (20 nm) using a Hummer I sputter coater and viewed with a Hitachi 5570 scanning electron microscope.

**Transmission electron microscopy.** HET1-A cells (5 x 10^5 cells) were cultured in tissue culture Petri dishes (40 mm; Nunc, VWR Scientific) containing 2 ml EPM2 medium for 48 h. Monolayers were washed with HBSS and infected with yeast cells as described above (see HET1-A adherence assay). After a 90 min incubation, non-adherent yeast cells were removed by washing monolayers three times with HBSS (pH 7.2). Subsequently, infected monolayers were fixed with 2% glutaraldehyde in HBSS for 1 h at room temperature. The monolayers were washed three times with HBSS, post-fixed with 2% osmium tetroxide for 1 h at 4 °C, and then dehydrated through a graded series of alcohols and embedded in situ with Epon (Ted Pella). Following polymerization of the Epon, the embedded monolayers were released from the tissue culture dishes by immersion in dry ice. Ultrathin sections were prepared, stained with lead citrate and examined using a JEOL 1200X transmission electron microscope.

**Growth of C. albicans in galactose or glucose.** Yeast cells were grown overnight at 30 °C in either YP-glucose or YP-galactose broth. Cells were washed with 0.2 M PBS, pH 7.2, adjusted to a concentration of 6.3 to 10^7 cells ml^-1 and inoculated into 20 ml of fresh YP broth containing either 500 mM D-galactose or 500 mM D-glucose to achieve a final concentration of 4 x 10^6 cells (ml YP broth)^-1. Growth of cultures in YP-
Adherence of Candida: galactose effect

galactose or YP-glucose was measured turbidimetrically (540 nm) at various times using an LKB Ultraspec II spectrophotometer. Duplicate readings were obtained for each time interval.

SDS-PAGE and immunoblotting. SDS-PAGE, under reducing conditions, and Western blotting were performed by previously established procedures (Wadsworth & Calderone, 1993) using β-mercaptoethanol (β-ME) cell extracts as samples. Extraction of proteins from C. albicans YP cultures containing either 500 mM D-galactose or D-glucose was done as described previously by Bailey et al. (1995). Equal amounts of proteins were separated on 10% (w/v) gels and electrotransferred to nitrocellulose membranes (0.45 μm). Blots were stained with Aurodye or immunoblotted with rabbit polyclonal IgG anti-whole C. albicans 4918 cells. For detection of immunoreactive proteins, anti-rabbit IgG-conjugated alkaline phosphatase was used as a secondary antibody, according to the manufacturer's protocol (Promega).

RESULTS

Adherence of C. albicans to HET1-A cells

We initially determined that following a 90 min incubation, approximately 11% of HET1-A cells had adhering Candida cells when the yeast cells were grown on YP-glucose agar. Because the amount of HET1-A cells with adhering Candida cells seemed low, we examined the influence of other carbon sources in YP medium on the adherence of yeast cells to HET1-A cells. In addition to D-glucose, we performed preliminary experiments on the adherence of yeast cells grown in YP medium containing D-galactose, D-maltose, D-xylose or trehalose. Further, the concentration of sugars was increased in these experiments to 500 mM, since other investigators have shown that adherence of C. albicans yeast cells to acrylics or HBEC was greatest in media supplemented with 500 mM D-galactose (McCourtie & Douglas, 1981, 1984). Of the sugars tested, we found that the highest adherence occurred with D-galactose-grown cells (data not shown). Thus, in all subsequent experiments, we compared only D-galactose- and D-glucose-grown organisms for their effects on adherence. We found that the adherence of D-

Fig. 2. Growth of C. albicans in YP-glucose (filled bars) versus YP-galactose (open bars) at 30 ºC.

The percentage of C. albicans inoculum which adhered to the HET1-A cells under optimum conditions was approximately 10%. The adherence of the D-glucose- or D-galactose-grown organism to HET1-A cells was studied over time (Fig. 1). With D-galactose-grown cells, adherence increased from approximately 10% at 30 min to 60% after 180 min. While the adherence at 90 min was not as great as at 180 min, we chose to use a 90 min incubation for subsequent experiments, since plastic-adherent yeast cells which had germinated tended to overgrow the HET1-A cells after a 90 min incubation.

In addition to the adherence studies with HET1-A cells, we measured the effect of galactose on the adherence of yeast cells to HBEC and a murine alveolar macrophage cell line (MH-S). These data are presented in Table 1. Adherence of yeast cells to HBEC and MH-S cells increased significantly when Candida was grown in YP-galactose compared to YP-glucose.

While D-galactose stimulated adherence of yeast cells, growth of C. albicans, as measured in YP-glucose broth at 30 ºC, was somewhat better than with cells grown in YP-galactose (Fig. 2).

Blocking experiments with sugars

Adherence of C. albicans to HBEC can be blocked in the presence of L-fucose or amino sugars depending upon the strain of the organism used (Critchley & Douglas, 1987b). We performed similar experiments by including N-acetyl-D-glucosamine, D-glucosamine, L-fucose, D-glucose, D-glucosamine, or L-fucose in the adherence assays. The data in Table 2 indicate that of the sugars listed above, N-acetyl-D-glucosamine or D-glucosamine inhibited the adherence of yeast cells to HET1-A cells by 40%. L-Fucose, by comparison, stimulated adherence. Similarly to C. albicans 4918, the adherence of other strains tested (A9 and 4918-2) was also inhibited by amino sugars (data not shown); however, L-fucose was not stimulatory as with strain 4918. In a separate experiment, we found that N-acetyl-D-glucosamine or D-glucosamine blocked adherence when preincubated with Candida but not with the HET1-A cells (data not shown).

Scanning and transmission electron microscopy

Following incubation of the organism with HET1-A cells for 60 min, we observed the adherence of yeast cells to HET1-A cells by light microscopy (Fig. 3a); additionally, the organism adhered to the tissue culture dishes in areas where HET1-A conflueny had not occurred. Adhering yeast cells (to plastic or HET1-A cells) had germinated by 90 min, although in many instances germination seemed to be somewhat inhibited when yeast cells adhered to HET1-A cells in comparison to plastic-adhered cells. We did not attempt to determine by light microscopy if the HET1-A cells phagocyted C. albicans, and, instead, used scanning and transmission electron microscopy to characterize these events. By scanning electron microscopy (Fig. 3b), the organism was observed to germinate on the surface of the HET1-A cells. In some instances, the germ tube of the organism appeared to be within an infolding of the HET1-A membrane (Fig. 3b; see arrowhead), somewhat suggestive of a phagocytic process. HET1-A cell membrane ruffling at the point of contact with yeast cells and/or germ tubes was not observed. We also used transmission electron microscopy to characterize the Candida-HET1-A cell interaction. We observed the presence of HET1-A pseudopodia only at the yeast cell–HET1-A cell junctions, again suggesting a phagocytosis process (Fig. 3c; see arrowheads) or what appeared to be the beginning of a phagocytic event (Fig. 3d). Also, electron-dense material of unknown origin was often observed between closely associated HET1-A and Candida cells (data not shown). As stated previously, longer incubation times preceded microscopic analysis because of the overgrowth of plastic-attached, germinating yeast cells.

SDS-PAGE and Western blotting

The protein profiles of the β-ME extracts from D-galactose- or D-glucose-grown yeast cells are shown in Fig. 4. An array of proteins differing in molecular mass is revealed in Aurodye-stained blots. A protein of approximately 190 kDa is observed only in the extract from D-galactose-grown cells (Fig. 4, lanes 1 and 2 vs lane 3). Likewise, in Western blots, the 190 kDa protein from D-galactose-grown cells only was strongly immunoprecipitated by the anti-Candida rabbit IgG (Fig. 4, lane 4 vs lane 5). Other quantitative as well as qualitative differences between the two preparations were also observed.

DISCUSSION

Oral, oesophageal and/or vaginal candidiasis in AIDS patients is extremely common. While a number of studies of Candida-buccal or oral epithelial cell interactions have been reported (summarized by Calderone & Wadsworth, 1993; Calderone & Braun, 1991), there is little, if any, information on the adherence of the organism to human oesophageal epithelial cells. We used an SV-40-transformed human epithelial cell line (HET1-A) to study this interaction. The utility of the HET1-A cells is that they retain cell surface markers typical of epithelial cells and, thus, can be useful in characterizing the recognition system used by Candida.

We observed that maximal adherence of the organism was time-dependent and influenced by the carbon source used in preparing the yeast cells. The percentage of HET1-A cells with adhering Candida increased when the organism was grown in YP-galactose broth in comparison to YP-glucose broth. Adherence was increased not only to HET1-A cells but also to HBEC and MH-S cells (a murine alveolar macrophage cell line). Our results with HBEC are similar to those described by McCourtie & Douglas (1981, 1984). These authors observed that when grown in 500 mM D-galactose, the cell surface of yeast cells assumed a pronounced fibrillar appearance not observed with cells grown in 50 mM D-glucose. Interestingly, the galactose effect on adherence was only observed with strains of C. albicans from active infections. Strains from asymptomatic carriers did not exhibit the galactose-induced increase in adherence (McCourtie &
Douglas, 1984). Growth of the organism in d-galactose also resulted in an increase in mortality among infected animals when strains from active infections were used; in contrast, strains from asymptomatic carriers did not exhibit the augmented virulence when grown in galactose. While microscopic observations of the surface phenotype of cells grown in d-galactose were made, McCourtie & Douglas (1984) did not determine if specific changes in cell wall protein profiles occurred in cells from the two different growth media. From culture supernatants of galactose-grown Candida, these investigators isolated an extracellular polymer which blocked the adherence of the organism to HBEC; also, the adherence of glucose-grown cells to acrylic increased when the acrylic was coated with extracellular polymer prepared from galactose-grown cells (McCourtie & Douglas 1985).

In the present study, light microscopic observations of HET1-A-infected cells demonstrated that the organism adhered to and eventually germinated directly on the HET1-A cells. Plastic-adherent yeast cells also germinated even though monolayers were extensively washed with HBSS and all adherence assays were done in HBSS. Germination of C. albicans on plastic catheters in a non-germinating medium has been reported by Hawser & Douglas (1994); our data would indicate a similar phenomenon.

Electron microscopic studies were done to characterize the Candida interaction with HET1-A cells. HET1-A cells formed pseudopodia-like structures when in close association with the organism, similar to the observation by Edwards et al. (1987) with human endothelial cells.

Fig. 4. SDS-PAGE and Western blot analyses of β-ME extracts from yeast cells grown in YP-glucose broth (lanes 1, 2 and 4) or in YP-galactose broth (lanes 3 and 5). Lanes: 1, 2 and 3, Aurodye stained; 4 and 5, Western blot using purified IgG from a polyclonal antiserum made in rabbits infected with C. albicans. Molecular mass standards are indicated.

The increased adherence of yeast cells grown in β-galactose suggested the possibility that specific changes in the cell surface proteins may have occurred. Results from SDS-PAGE analyses verified this idea. A 190 kDa protein present only in β-ME extracts from cultures grown in β-galactose was observed. We are currently characterizing this protein to determine its role in adherence.

ACKNOWLEDGEMENTS

The authors wish to acknowledge that this work was supported by a US Public Health Service grant (NIH-NIAID PO1AI37251) to R.C. and by the Lombardi Cancer Research Center Cytotechnology and Morphology Core Facility, US PHS Grant 1P30-CA-51008. The authors also wish to thank Dr Curtis Harris, National Cancer Institute, for providing the HET1-A cell line and Dr K. Sankaran for providing the MH-S cells.
