The role of actin in apical growth and enzyme secretion in the filamentous fungus Aspergillus nidulans was studied by treating the hyphae with cytochalasin A (CA), which inhibits actin polymerization. Indirect immunofluorescence microscopy revealed actin at the tips of main hyphae and branches, and at the sites of developing septa. CA inhibited the growth of the fungus and changed the growth pattern of hyphal tips from cylindrical tubes to spherical beads. The regions with swellings showed no actin fluorescence, and neither was actin seen in association with septa. After 4 h exposure, hyphae were able to resume the normal tip growth pattern in the presence of CA for a short period of time and new cylindrical hyphae, with actin fluorescence at the apex, emerged from the swollen tips. Later, the tips of the hyphae swelled again, which led to a beaded appearance. We also studied the effect of CA on the secretion of α- and β-galactosidase. α-Galactosidase is secreted into the culture medium, whereas β-galactosidase remains in the mycelium, with part of its activity bound to the cell wall. When A. nidulans mycelium was incubated in the presence of CA, a reduction in the secretion of α-galactosidase into the culture medium and a decrease in the α- and β-galactosidase activities bound to the cell wall was detected. However, the CA dose used for the hyphae did not modify the secretion of the enzymes from protoplasts. Results described here provide evidence that a polymerized actin cytoskeleton is required for normal apical growth, hyphal tip shape and polarized enzyme secretion in A. nidulans. Cytochalasin-induced disruptions of the actin cytoskeleton could result in the alterations of apical growth and inhibition of enzyme secretion observed by blocking secretory vesicle transport to the apex.

Keywords: actin, cytochalasin, Aspergillus nidulans, α-galactosidase, β-galactosidase

INTRODUCTION

A characteristic of many filamentous fungi is their ability to secrete large amounts of proteins into the culture medium. Fungal exoenzymes are used in a variety of industries, especially in relation to food (Lowe, 1992). The ability of filamentous fungi to secrete enzymes into the culture medium has also made them attractive candidates as hosts for heterologous protein production, since enzyme secretion facilitates purification (Archer & Wood, 1994).

Our understanding of the molecular mechanisms regulating protein secretion in filamentous fungi is still very limited, but it has been proposed that the major stages and compartments of the secretion process in filamentous fungi are probably similar to those identified in budding yeast and other eukaryotic cells (Sheckman & Novick, 1982; Pryer et al., 1992). Indications for this come from analysis of the hyphal ultrastructure of various fungi grown under conditions that promote efficient protein secretion (Punt et al., 1994). Most of the
extracellular fungal enzymes are glycoproteins. In budding yeast, following synthesis in the rough endoplasmic reticulum, where the initial steps of glycosylation occur, proteins are transported to the Golgi apparatus, where further glycosylation takes place (Tanner & Lehle, 1987). Proteins are packaged within vesicles that are transported to the cell surface, where they fuse with the plasma membrane, liberating their contents to the periplasmic space. Proteins may then remain within the periplasmic space, be retained at the mature cell wall, or pass through the cell wall into the medium (Farkas, 1987).

Protein secretion is related to fungal growth. Yeast mutants specifically blocked in secretion are defective in cell-surface expansion (Novick & Sheckman, 1983). In filamentous fungi, growth and protein secretion are polarized processes mainly restricted to the growing hyphal tips (Wosten et al., 1991), where the cell wall is more porous than in the mature wall, perhaps allowing the rapid diffusion of proteins (Chang & Trevithick, 1974; Wessels, 1993). Little is known about the mechanism involved in polarized vesicle movement to the hyphal tip, although several studies implicate cytoskeletal components in the process (Howard & Aist, 1980). In hyphae, predominant components of the cytoskeleton are microtubules and actin (Salo et al., 1989; Heath, 1990, 1994). A straightforward approach to determine the role of cytoskeletal components on growth and secretion is to disrupt them with specific inhibitors and examine the effects. Benzimidazole-derived anti-microtubular drugs, such as benomyl, have been used to study the role of microtubules on growth and protein secretion in filamentous fungi. However, these studies have not led to conclusive results (Howard & Aist, 1980; Monistrol et al., 1988; Peterbauer et al., 1992; Jochová et al., 1993; Pedregosa et al., 1995; Torralba et al., 1996). Cytochalasins are known for their ability to inhibit polymerization of actin in vivo and can be used to study the functions of the actin cytoskeleton (Srinivasan et al., 1996). Among cytoskeletal components, actin seems to be the most important for apical growth in yeast and in filamentous fungi (Heath, 1990). Actin has been localized in filamentous fungi by immunological and related methods at the sites of wall formation such as at hyphal tips and at sites of septum formation (Runenberg et al., 1986; Butt & Heath, 1988; Bourett & Howard, 1991; Raudaskoski et al., 1991; Czynmek et al., 1995; Srinivasan et al., 1996).

In this work we studied the effect of cytochalasin A (CA) on apical growth and enzyme secretion in Aspergillus nidulans. This fungus is a good model for the study of the role of fungal actin since A. nidulans has only a single gene that encodes a γ-actin (Fidel et al., 1988) and CA has been shown to block septum formation in this fungus (Harris et al., 1994). We studied the effect of CA on the secretion of two hydrolytic enzymes from A. nidulans: α-galactosidase, which is secreted into the culture medium (Rios et al., 1993), and β-galactosidase, which remains in the periplasmic space and bound to the cell wall (Fantes & Roberts, 1973; Torralba et al., 1996).

The cell wall plays an important role in controlling secretion in filamentous fungi (Peberdy, 1994), which makes it necessary to quantify not only the levels of enzyme released into the culture medium, but also the portion of secreted protein bound to the cell wall. The analysis of secretion was completed with an immunocytochemical study of actin distribution in the hyphae of A. nidulans grown in the presence and absence of the drug. The results support the idea that actin plays a role in apical growth and secretion in A. nidulans.

METHODS

Fungal strains and culture media. Aspergillus nidulans (Eidam) Winter wild-type strain 2.3, kindly provided by Professor J. F. Peberdy (University of Nottingham, UK) was used in this study. Several culture media were used. Stock cultures were maintained on MYG agar (0.5% malt extract, 0.25% yeast extract, 1% glucose, 2% agar). The medium used in microscopy studies was MYL (0.5% malt extract, 0.25% yeast extract, 1% lactose, 2% agar). Aspergillus liquid minimal medium (AMM) (Pontecorvo et al., 1953), supplemented with glucose or lactose (1%, w/v) as the carbon source, was used in the secretion experiments. CA (Sigma) was dissolved in DMSO and diluted to a final stock concentration of 5% in DMSO. The concentrations of cytochalasin used in this study varied from 1 to 500 µg ml⁻¹ and were obtained by dilutions of the stock solution. Solvent concentration in the medium was never more than 0.1% (v/v). Control experiments with DMSO did not show any detectable alteration as compared to the control without the solvent.

Growth measurements. The growth of A. nidulans in the presence of different concentrations of CA (10, 20, 50, 80 and 100 µg ml⁻¹) was studied in both solid and liquid media. The effect of CA on mycelial growth was first tested in solid medium by inoculating MYL agar, with or without the drug, with small agar plugs taken from the edge of actively growing mycelial colonies of A. nidulans. Cultures were grown at 28 °C for 72 h. The diameters of the colonies were measured periodically and the growth at the different times of incubation was expressed as the mean diameter of ten colonies. Fungal growth of A. nidulans in liquid medium in the presence of several doses of CA was studied by determination of freeze-dried weight. Preliminary experiments (data not shown) had indicated that CA prevented germination of conidia from A. nidulans. Therefore conidia were allowed to germinate and grow in liquid AMM supplemented with lactose for 48 h on an orbital shaker at 200 r.p.m. at 28 °C. CA was added to the media and cultures were grown for 72 h in the absence or presence of different concentrations of the drug. Samples were taken periodically. Mycelia were harvested by filtration through Whatman no.1 paper, washed with distilled water and freeze-dried.

Enzyme activity measurements. Several methods to induce α-galactosidase (EC 3.2.1.22) and β-galactosidase (EC 3.2.1.23) production and secretion in A. nidulans were tested. The procedure presented below was finally chosen since it allowed quantification of CA effects on production and secretion of enzymes. Conidia were harvested from MYG agar plates and transferred to liquid AMM supplemented with glucose (1%, w/v) as the carbon source. Cultures were grown on an orbital shaker at 200 r.p.m. at 28 °C for 48 h in this medium and then transferred to AMM supplemented with 1% lactose for α- and β-galactosidase induction. The cultures were incubated in the lactose medium for 40 h in the absence
and presence of 80 μg CA ml\(^{-1}\). During growth, control and treated cultures were harvested periodically.

To test enzyme production and distribution in A. nidulans hyphae, three fractions were derived from the cultures, according to previously reported methods (Torralba et al., 1996): two fractions were from the mycelium, namely the soluble and insoluble mycelial fractions, and the third fraction was a culture filtrate preparation. The mycelium was separated from the liquid culture by filtration through nylon membranes, washed in 0.5 M Tris/phosphate buffer (pH 6.7), frozen and freeze-dried. The freeze-dried mycelium was weighed to determine its biomass. Cell extracts were obtained by grinding the freeze-dried mycelia in liquid nitrogen to a fine powder with pestle and mortar. The powdered mycelia were suspended in lysis buffer: 0.5 M Tris/phosphate pH 6.7 containing 10% (v/v) glycerol, 0.1 mM dithiothreitol and 2.5 mM PMSF. Cell extracts were centrifuged and the supernatant obtained was used as the soluble mycelial fraction. The pellet was washed three times with lysis buffer, resuspended in the buffer and used as insoluble mycelial fraction (wall fraction) (Vainstein & Peberdy, 1991). Enzyme activities were determined from all three fractions.

Enzyme distribution was also studied in protoplasts. Protoplasts were prepared in a lytic solution containing an enzyme solution containing 5 mg lysing enzymes ml\(^{-1}\) from Trichoderma harzianum (Sigma) in 0.6 M KCl. After 3 h gentle agitation at 28 °C the protoplasts were harvested, washed and transferred to AMM containing 1% lactose, 0.6 M KCl and CA at different concentrations (0, 80, 100 and 500 μg ml\(^{-1}\)). The final concentration of cells was adjusted at 10\(^{6}\) protoplasts ml\(^{-1}\) and protoplasts were incubated at 28 °C for 50 h. Protoplast growth and regeneration was monitored by phase-contrast microscopy. Enzyme secretion was studied during the first 20 h incubation, in which the protoplasts did not show tip growth and remained unregenerated. Periodically, protoplasts were separated from culture medium by low-speed centrifugation, washed with 0.6 M KCl and lysed in distilled water in the presence of 0.6 M Tris/phosphate pH 6.7. The material suspended in the insoluble mycelial fractions was removed by centrifugation before spectrophotometric determinations, to avoid interference with the assays. Enzyme units are defined as the amount of enzyme liberating 1 μmol p-nitrophenol min\(^{-1}\). Total enzyme activity was calculated in units per mg freeze-dried mycelium or per 10\(^{6}\) protoplasts. Enzyme activities in the different fractions are expressed as a percentage of the total activity in the cultures. Results are given as the mean of three independent experiments. Two replicate samples were analysed for each determination.

### Indirect immunofluorescence (IIF) microscopy

For the visualization of actin and DNA in the hyphae, colonies of A. nidulans were grown overnight at 37 °C on MYL agar medium on small pieces of dialysis membrane covered with 0.5% (w/v) agarose (Raudaskoski et al., 1991). For exposure of the mycelium to the inhibitor, membranes with small colonies were transferred to MYL plates containing 20 μg CA ml\(^{-1}\) for 6 h. To handle the control and treated colonies similarly, all the control colonies were also transferred to new control plates. The colonies were frozen and freeze-substituted in methanol containing 3:7% formaldehyde, as described by Raudaskoski et al. (1991). After freeze substitution for 2 d, the samples were gradually rehydrated and prepared for immunolabelling with antiactin N350 monoclonal antibody (Amersham) according to the methods of Raudaskoski et al. (1991). The nuclei and cross-walls were stained by 4',6-diamidino-2-phenylindole (DAPI, Sigma) and calcofluor (Polysciences), respectively. At least 400 apices were examined in each sample for actin fluorescence. The figures show results typical from at least three different labelling experiments.

### RESULTS AND DISCUSSION

#### Effect of CA on growth of A. nidulans

The primary effect of cytochalasins is the inhibition of actin polymerization (Srinivasan et al., 1996) but these compounds also affect functions not yet known to be related to the actin cytoskeleton, such as glucose transport across cell membranes (Lin & Spudich, 1974) and mitochondrial respiration (Manavanthu et al., 1980). In the present work, the effect of different concentrations of CA on the growth of A. nidulans mycelium in both solid (Fig. 1) and liquid media was studied. The concentration of the drug that inhibited growth by 30% was chosen for the experiments and its effect on the actin cytoskeleton was confirmed by IIF microscopical studies.

---

**Fig. 1.** Growth of A. nidulans in the absence or presence of CA on solid medium. ○, Control; ■, CA at 10 μg ml\(^{-1}\); ▲, CA at 20 μg ml\(^{-1}\); ♂, CA at 50 μg ml\(^{-1}\); ×, CA at 80 μg ml\(^{-1}\); ●, CA at 100 μg ml\(^{-1}\); se were less than 10% of the mean.
In MYL plates, a sublethal dose of 20 µg CA ml⁻¹ caused 30% growth inhibition and was chosen for IIF microscopical studies, for which the mycelium was grown on solid medium. In liquid medium, increasing amounts of CA progressively reduced growth, but higher doses of CA were required to obtain growth inhibition similar to that in solid medium (data not shown). In liquid medium, 80 µg CA ml⁻¹ was required to obtain 30% inhibition of growth and therefore this concentration was chosen for studies of secretion.

Effect of CA on hyphal morphology and actin distribution

IIF microscopical studies of control hyphae of A. nidulans visualized actin at sites of wall growth, at hyphal and branch apices (Fig. 2a–c, e), and at the sites of developing septa (Fig. 2f–i). Similar actin distribution has been detected previously in A. nidulans germ tubes (Harris et al., 1994; McGoldrich et al., 1995), and also in the hyphae of other filamentous fungi and in yeast cells by using IIF techniques and/or fluorescently labelled phallotoxins (Hoch & Staples, 1983; Adams & Pringle, 1984; Marks & Hyams, 1985; Runeberg et al., 1986; Tucker et al., 1986; Butt & Heath, 1988; Salo et al., 1989; Raudaskoski et al., 1991; Roberson, 1992; Srinivasan et al., 1996).

Antiactin antibodies revealed strong actin fluorescence at the tip of 98% of the main hyphae and branches of A. nidulans (Fig. 2a). Most of the previous studies in yeast and filamentous fungi visualized actin as plaques or peripheral dots, whereas the present study also showed areas with more homogeneous actin fluorescence (Fig. 2c), which could be due to differences in the fixation methods used. The comparison of actin fluorescence and calcofluor staining of developing septa indicated that at initial stages of septum formation, actin formed a dense double band (Fig. 2f, g). During the development.

Fig. 2. Control hyphae of A. nidulans. (a) Immunofluorescence of actin at hyphal tips; (b–d) phase-contrast microscopy (b), IIF microscopy with antiactin antibody (c), and DAPI-staining (d) of the same hyphal tip; (e) actin localization in main hyphal tip and a branch tip; (f–i) IIF microscopy with antiactin antibody (f, h) and calcofluor staining (g, i) of two septa, at early (f, g) and advanced (h, i) stages of septum development. Bars, 5 µm.
Effects of cytochalasin A on *Aspergillus nidulans*

Fig. 3. Hyphae of *A. nidulans* treated with CA at 20 μg ml⁻¹. (a) Colony edge after 4 h growth on CA medium; (b–d) phase-contrast microscopy (b), IIF microscopy with antiactin antibody (c) and DAPI staining of nuclei (d) in the same swollen hypha after 3 h CA treatment [note the lack of actin fluorescence from swollen part of the hypha (c), and nuclei accumulating in swollen tips (d)]; (e, f) phase-contrast microscopy (e) and IIF microscopy with antiactin antibody (f) of the same hyphae after 4 h CA treatment showing resumption of apical growth from a swollen tip; (g, h) phase contrast (g) and actin staining (h) of hypha in a more advanced stage of apical growth on CA-containing medium. Bars, 5 μm.

of the septum, actin fluorescence decreased and only two rows of actin spots were seen associated with septa in more advanced stages of formation (Fig. 2h, i). Fully developed septa were stained only with calcofluor and not with antiactin antibody (not shown).

When colonies of *A. nidulans* were grown overnight on control medium and then transferred to MYL plates containing 20 μg CA ml⁻¹, the form of the apices changed from cylindrical to spherical and the tip of apical cells became swollen (Fig. 3a–d). Swelling of the hyphal tip due to cytochalasin treatment has been reported in several filamentous fungi (Oliver, 1973; Allen *et al.*, 1980; Grove & Sweigard, 1980; Tucker *et al.*, 1986; Srinivasan *et al.*, 1996). In *Saccharomyces cerevisiae*, spherical expansion without budding was reported in mutants with defects in actin (Novick & Botstein, 1985) and actin-related proteins (Johnston *et al.*, 1991), which suggests that the morphological changes that were observed in the *A. nidulans* hyphae were likely to result from the action of CA on actin. This was further supported by the lack of actin fluorescence from swollen tips (Fig. 3c). Hyphae of *A. nidulans* were able to return for periods to a normal pattern of growth.
in the presence of CA. New normal-looking cylindrical hyphae formed from the spheres were observed in 80% of hyphae in 4 h samples (Fig. 3c–h) and staining with antiactin antibodies was detected in 23% of the apices with cylindrical growth pattern. Several of the tips showed a stronger actin fluorescence than the control hyphae (Fig. 3f, h). The irregular beady appearance of the hyphae grown for 4 h in the presence of CA (Fig. 3a, e) suggested that the tips would swell again after a period of normal growth.

In the presence of CA, colony expansion appeared to accelerate with time (Fig. 1). This could be due to either the adaptation of A. nidulans to cytochalasin treatment or breakdown of the drug in the medium. *Aspergillus niger* has been reported to adapt to several antifungal agents for reasons not yet clarified (Park et al., 1994, 1996). In *A. nidulans*, the cyclic alterations in the immunolocalization of actin at the tip of *A. nidulans* hyphae grown in presence of CA correlated well with the normal and abnormal growth pattern of the hyphal tip (Fig. 3), and suggested that the actin cytoskeleton could reassemble and normal apical growth resume for short periods of time in the presence of CA. Whether this pattern of adaptation to CA is related to the different phases of the cell cycle in the hyphae and could be involved in the accelerated expansion of the colonies during prolonged incubation on CA-containing medium has to be clarified in the future.

CA is known to alter the distribution of actin during the germination of *Candida albicans* (Akashi et al., 1994) and *Neurospora crassa* (Barja et al., 1991). However, actin location in *Uromyces phaseoli* (Tucker et al., 1986) and *Saprolegnia ferax* (Jackson & Heath, 1990) was not disturbed by treatment with cytochalasin E. Harris et al. (1994) observed that CA inhibited septum formation in germlings of *A. nidulans*. Careful examination of CA-treated hyphae with a beaded growth pattern failed to show formation of septa or actin fluorescence associated with septa (not shown). This suggests that the function of actin in the development of septa is more sensitive to CA than it is in the tip growth.

In the control hyphae of *A. nidulans*, the nuclei occurred at a certain distance from the hyphal tip apex (Fig. 2b, d) but in hyphae treated with CA, the distribution of nuclei was abnormal. The nuclei aggregated in the spherical germination of *A. nidulans*, secreted α-galactosidase activity was detected in 23% of the apices with septa or actin fluorescence associated with septa (not shown). This suggests that the function of actin in the development of septa is more sensitive to CA than it is in the tip growth.

**Effect of CA on production and distribution of enzymes in A. nidulans**

Total α-galactosidase and β-galactosidase activities started to increase significantly only after 8 h incubation of mycelia in media with lactose as a carbon source. When the fungus was incubated in the presence of CA (80 µg ml⁻¹), enzyme production started at the same time as in the control culture, but about a 30% reduction of the total activity of the enzymes was observed over 40 h for reasons not yet known (Table 1).

The distribution of the α- and β-galactosidase activities in the three fractions obtained from the fungal cultures during the incubation of *A. nidulans* mycelia, with or without 80 µg CA ml⁻¹, is shown in Fig. 4. The activities determined in the culture filtrates, soluble mycelial and cell wall fractions are expressed as the percentage of the total activity. During the exponential growth of *A. nidulans* mycelium, secreted α-galactosidase activity was detected in the culture medium (Fig. 4a) and in the insoluble mycelial fraction (Fig. 4b), which agrees with previously reported results (Rios et al., 1993). When the fungus was grown in the presence of CA, the enzyme activity in the culture filtrate and cell wall fraction was reduced (Fig. 4a, b) while α-galactosidase activity in the soluble mycelial fraction was found to increase (Fig. 4c).

No β-galactosidase activity was detected in culture filtrates (Fig. 4d), which agrees with the previous work (Fiedurek & Ilczuk, 1990) and shows that β-galactosidase activity is not released to the culture medium. However, recent studies (Diaz et al., 1996, Torralba et al., 1996) have located this enzyme external to the cell.
membrane, demonstrating that it has to be considered as a secreted enzyme, although not released to the supranatant. Our studies of enzyme distribution in *A. nidulans* mycelium showed that in control cultures around 10% of the total β-galactosidase activity was detected in the insoluble mycelial fraction. However, less than 5% of the total activity appeared bound to the cell wall in presence of CA (Fig. 4c). Besides, accumulation of the enzyme activity in the soluble mycelial fraction was observed in CA cultures (Fig. 4f). Our results suggest that the secretion of both α- and β-galactosidase from *A. nidulans* mycelium was significantly decreased in the presence of CA. This agrees with a previous report which described inhibition of cellulase synthesis and secretion by CA in the oomycete *Achylya* (Thomas et al., 1974).

In protoplasts, total enzyme activities were not affected by the presence of 80 μg CA ml⁻¹. After 16 h of enzyme induction, the total α-galactosidase activity was 9.3 mU ml⁻¹ in the control and 8.9 mU ml⁻¹ in the presence of CA. β-Galactosidase activities in untreated and treated cells were 0.25 and 0.26 mU ml⁻¹, respectively. About 60% α-galactosidase and 80% β-galactosidase activity was secreted to the medium by protoplasts (data not shown). The activities of α- and β-galactosidase in the extracellular medium were not due to lysis of protoplasts, since no activity of the intracellular enzyme malate dehydrogenase was detected in the culture medium. Therefore the α- and β-galactosidase activities measured in the culture medium must represent active secretion of proteins from the protoplasts. In contrast to the mycelium, no clear difference occurred in enzyme secretion between control protoplasts and protoplasts treated with 80 μg CA ml⁻¹ (data not shown). In addition, higher concentrations of CA (100, 200 and 500 μg ml⁻¹) did not modify either enzyme production or secretion by protoplasts. However, CA may have some effect on the actin cytoskeleton in protoplasts, since cell wall formation and tip growth were delayed in CA-treated protoplasts compared to the control, as observed by phase-contrast microscopy (not shown).

Cytochalasin-induced disruptions of the actin cytoskeleton, indicated by IIF microscopical studies, could result in the alterations of hyphal morphology and inhibition of enzyme secretion observed here. The disturbances in the actin cytoskeleton may block secretory vesicle transport to the apex. In another tip-growing cell, the movement of comparable vesicles was inhibited by cytochalasins (Lancelle & Hepler, 1988). However, one might not expect a similar transport of vesicles in secretion by protoplasts, which could help explain the unchanged level of secretion observed here in the presence of CA. These results would support the hypothesis that actin has a primary role in the movement of secretory vesicles in filamentous fungi. *S. cerevisiae* mutants with defects in the actin cytoskeleton showed accumulation of secretory vesicles (Novick & Botstein, 1985; Johnston et al., 1991; Liu & Bretscher, 1992) and inhibition of invertase secretion (Novick & Botstein, 1985).

Our results support the hypothesis that actin has a primary role in the movement of secretory vesicles in fungi and that an actin-based system controls the polarity of hyphal growth and secretion in *A. nidulans*. This is also supported by the involvement of a novel myosin I in polarized growth and secretion in *A. nidulans* (McGoldrich et al., 1995). However it has been suggested that microtubules are also involved in these processes in filamentous fungi (Howard & Aist, 1980; Raudaskoski et al., 1994; Rupes et al., 1995; Pedregosa et al., 1995) including *A. nidulans* (De Lucas et al., 1993; Jochova et al., 1993; Tórralba et al., 1996). Therefore, further studies should be done to establish the definitive role and possible interrelations of microtubules, actin and myosin during fungal growth and protein secretion.
