Loss of heterozygosity, by mitotic gene conversion and crossing over, causes strain-specific adenine mutants in constitutive diploid Candida albicans

P. W. K. Tsang, B. Cao, P. Y. L. Siu and J. Wang

Molecular evidence is provided in this paper to elucidate a long-standing intriguing phenomenon in fungal genetics: that many natural isolates of the constitutive diploid organism Candida albicans yield strain-specific, recessive mutants at a reproducible frequency that is as high as a few percent of the surviving cells after exposure to UV irradiation or other mutagens. Southern hybridization analysis and DNA sequence data indicated that C. albicans CA12, a clinical isolate, is heterozygous for the ADE2 gene, carrying one functional and one null allele. Sequence analysis of the null allele revealed the presence of a 13 kb deletion, which locates between two AATC repeats and spans the promoter and coding regions of the gene. The adenine auxotrophic mutants, which were readily isolated after UV irradiation of C. albicans CA12, were proved to be the segregants of mitotic recombination as they remained as diploid, not hemizygous or haploid, cells and were homozygous for ade2. Analysis of reciprocal products of the mitotic recombination detected that the process of loss of heterozygosity was mediated by mitotic crossing over (reciprocal exchange of genetic information) as well as gene conversion (non-reciprocal exchange of genetic information).

Keywords: Candida albicans, loss of heterozygosity, adenine auxotroph, gene conversion, mitotic crossing over

INTRODUCTION

Candida albicans, the most common human fungal pathogen, is responsible for the majority of candidiasis (Odds, 1994). This opportunistic pathogen is part of the normal flora in the mouth, vaginal and gastrointestinal tracts in individuals with intact humoral and cellular immunity (Matthews, 1994), but becomes an invasive pathogen in people with a variety of transient or permanent immunocompromised conditions, including transplant recipients, chemotherapy patients, underweight neonates and HIV-infected individuals (Wickes & Petter, 1996). Molecular genetic, parasexual genetic and biochemical data have demonstrated that the fungus is an obligate diploid (Riggsby et al., 1982; Poulter, 1995), and there is no confirmed report of a haploid cell or sexual life cycle for the organism. A population-genetic study based upon isozyme-polymermorphism analysis has confirmed that the fungus reproduces by clonal propagation (Pujol et al., 1993). The unique biology and the close relationship between oropharyngeal candidiasis and AIDS development (Coleman et al., 1993) have made the organism one of the current focuses in basic and medical research (Braun & Johnson, 1997; Corner & Magee, 1997; Lo et al., 1997; Stoldt et al., 1997; Gale et al., 1998).

It has been observed that many C. albicans natural isolates are prone, after UV or chemical mutagenesis, to yield strain-specific, recessive mutant derivatives at high frequencies (Poulter, 1995). The most common mutant found was auxotrophic for sulfite reduction, followed by mutants auxotrophic for adenine, uracil, cytosine, isoleucine-valine, proline and methionine (Poulter, 1987). Mutants in colony morphology and resistance to 5-fluorocytosine have also been reported (Defever et al.,...
It has been estimated that at least 10% of C. albicans isolates exhibit certain types of auxotrophic heterozygosity (Scherer & Magee, 1990). Based on their extensive genetic studies on UV-induced amino acid auxotrophs in C. albicans FC18, Whelan et al. (1980) hypothesized that the relevant biosynthetic alleles of this strain were indigenously heterozygous, carrying one copy of the wild-type and one copy of the defective allele, and that the mutantogenesis promoted mitotic crossing over, resulting in homozygosity of the defective alleles. The auxotrophic heterozygosity is not limited to C. albicans, but has also been recorded in other fungi including Candida parapsilosis (Whelan & Kwon-Chung, 1988) and Candida krusei (Cao et al., 1997). The physiological significance of natural fungal heterozygosity remains elusive.

In this paper, we report genetic and molecular evidence that (1) the C. albicans clinical isolate CA12 is heterozygous at the ADE2 locus, (2) the strain-specific ade2 mutants are due to the homozygosis of ade2 and (3) gene conversion may play a dominant role in the homozygosis of ade2.

**METHODS**

*C. albicans* strains and plasmids. C. albicans clinical isolates CA11, CA12, CA13 and CA14 were all oral isolates recovered from HIV-infected patients in a local hospital and were obtained from Drs D. Tsang (Queen Elizabeth Hospital, Kowloon, Hong Kong) and L. P. Samaranayake (Faculty of Dentistry, University of Hong Kong). C. albicans hOG24 (ade2 pro1 met1; Poulter & Rikkerink, 1983) and hOG300 (ade2 pro1 met1; Kurtz et al., 1987), plasmids pRC2231 (Cannon et al., 1992) and pSM7 (Kurtz et al., 1986) were obtained from Dr R. D. Cannon (University of Otago, New Zealand).

UV mutagenesis and isolation of fungal sectors. Yeast cells in their early-exponential phase were spread onto the surface of YM plates (0·3 % yeast extract, 0·3 % malt extract, 0·5 % peptone, 1 % glucose and 2 % agar) at a density of approximately 10^6 cells per plate (15 cm diameter) and were immediately exposed to UV light for 75 s at a distance of 60 cm, equivalent to a dosage of 0·180 mW cm^{-2} s^{-1} as measured by an IL1430 health-hazard radiometer (International Light). Ade auxotrophs appeared as red-coloured colonies or colony sectors on YM plates after 3–4 d incubation at 37 °C. The white sectors of the sectored fungal colonies were purified as completely as possible and transferred into 1 ml water using a sterilized transfer needle or a flat toothpick. Care was taken to avoid contamination from the red sectors. Aliquots of the fungal suspension were spread on YM plates after briefly vortexing the suspension to mix the cells. Single white colonies were randomly chosen for further genetic analysis.

**Parasexual analysis.** The procedure of protoplast fusion was essentially as described by Saracheck et al. (1981). The test strains were C. albicans hOG24 (ade1 pro1 met1) and hOG300 (ade2 pro1 met1). Two partner fungal cells were grown separately in 20 ml YM until the OD_{600} reached 1·0. After harvesting by centrifugation at 1500 g for 5 min, the cell pellets were washed twice with sterile distilled water, resuspended in 2 ml PC solution (0·1 M phosphate, 0·05 M citrate buffer, pH 5·3, containing 1 % β-mercaptoethanol) and rotated at 160 r.p.m. on an orbital shaker at 37 °C for 30 min. The cells were then washed twice with 10 ml KB solution (0·6 M KCl in 0·1 M phosphate, 0·05 M citrate buffer, pH 5·3), resuspended in 2 ml KB solution and 120 μl lysate solution (10 mg ml^{-1}, Sigma, in KB solution). The enzyme mixture was incubated at 37 °C for 15–30 min at 160 r.p.m., washed with 3 ml KB solution, resuspended in 5 ml fusion mix (40 % PEG 3350, 10 mM CaCl_{2} and incubated at 37 °C at 160 r.p.m. for 30 min. The cell pellets were collected by centrifugation, resuspended in 800 μl KBC solution (0·6 M KCl and 10 mM CaCl_{2} in 0·1 M phosphate, 0·05 M citrate buffer, pH 5·3) and spread onto GSB plates (1·5 % glucose, 0·1 % ammonium sulfate, 0·2 % potassium dihydrogen phosphate, 0·005 % magnesium sulfate, 0·005 % calcium chloride, 0·001 % biotin and 1 ·5 % agar (Noble), supplemented with 1 % sorbitol. The fusion products appeared as white colonies on the plates after 3–4 d incubation at 37 °C.

**Isolation and sequencing of the ADE2 gene.** PCR reaction mixtures (50 μl) for amplification of ADE2 and ade2 contained 1–5 ng fungal genomic DNA, 10 ng each of two primers, P9 (5'-CTT GAC GAA AAC TGA ATT TAT TAC C-3') corresponding to nucleotide position 9–33 and CR2244 (5'-CTA TTT TTT CAA TTT ATC AGT TAA-3') corresponding to position 2221–2244 of the ADE2 gene (Genbank accession no. U75382). 0·2 mM dNTP, PCR buffer (10 mM Tris/HCl, pH 8·3, 50 mM KCl and 1·5 mM MgCl_{2}) and 2·0 units Taq DNA polymerase. Reactions were carried out under the following conditions: 94 °C, 1 min 30 s; 56 °C, 1 min 30 s; 72 °C, 2 min 15 s for 35 cycles. The DNA template was denatured for 2 min at 100 °C before it was mixed with the polymerase. After PCR and gel electrophoresis, the desired PCR fragment was excised and purified using a GeneClean II kit (BIO 101). Purified PCR products were cloned into pCRII, and sequenced using a T7 Sequencing Kit (Pharmacia Biotech). Nucleotides of the gene were numbered as described in the Genbank entry with the first nucleotide of the starting codon at position 541.

**Hybridization probe.** A 2·2 kb PCR fragment was amplified from C. albicans CA12 using primers P9 and CR2244 and cloned into pCRII (Invitrogen) to generate plasmid pCBY101. A 2·2 kb KpnI–EcoR V fragment from pCBY101 containing the ADE2 gene was used as the ADE2 probe in hybridization experiments.

**C. albicans DNA transformation.** DNA transformation was performed as described by Goshorn et al. (1992) with minor modifications. A 2·2 kb PCR fragment containing DNA sequence from position 59–2244 of the ADE2 gene was amplified using primers P59 (5'-ATG GTT AAT ATT TTT GCT TGA TGA T-3'), corresponding to nucleotide position 59–83, and primer CR2244. The PCR fragment was purified from agarose gel and used for the transformation. Fungal protoplasts were prepared by digesting exponential-phase fungal cells with lyticase for 1 h at 37 °C. One hundred microlitres of protoplast suspension was mixed with 10 μg transforming DNA, together with 40 μg calf thymus DNA as carrier, and incubated at room temperature for 15 min. Afterwards, 800 μl 40 % PEG 3350 in 10 mM CaCl_{2} was added, incubated at room temperature for 15 min, and mixed with 5 ml soft agar (containing GSB medium, 1 % sorbitol and 0·8 % agar (Noble)), and poured onto GSB agar plates. Transformants were scored after 3 d incubation at 37 °C. The transformation frequency was 5–10 transformants per microgram of PCR DNA.
RESULTS

Generation of ade2 mutants from C. albicans CA12 by UV irradiation

C. albicans, Saccharomyces cerevisiae and Ustilago maydis ade2 or ade1 mutants appear as red colonies on media deficient in adenine (Silver & Eaton, 1969; Poulter et al., 1981; Kronstad et al., 1989). After screening four C. albicans isolates (CA11, CA12, CA13 and CA14) isolated from local HIV-infected patients, we found that one of them, C. albicans CA12, consistently gave rise to such red adenine auxotrophs at a frequency of 2–6% of the surviving cells following UV irradiation as specified in the Methods. Two thousand surviving cells were randomly selected and replica plated on YM agar, a complete medium, and GSG agar, a minimal medium, and no auxotrophic mutants other than the red adenine mutants were detected. The three other C. albicans strains including CA11 were also subjected to the same UV treatment but no red Ade− mutants were detected.

No spontaneous red adenine auxotroph was detected among more than 100 000 CA12 cells. Protoplasts were prepared from the Ade− derivatives of CA12 and fused individually with the protoplasts of C. albicans hOG24 (ade1 pro1 met1; Poulter & Rikkerink, 1983) and hOG300 (ade2 pro1 met1; Kurtz et al., 1986). All the Ade− derivatives of CA12 tested formed fusants, which grew as white colonies on GSG plates, with hOG24, but not with hOG300. The adenine mutants were also rescued by transformation of integrative plasmid pSM7 (Kurtz et al., 1986) or self-replicating plasmid pRC2231 (Cannon et al., 1992), both of which carry the C. albicans Ade2 gene.

C. albicans CA12 carries natural heterozygosity at Ade2

Genomic DNA was extracted from CA12 and CA11, as well as from two of the randomly selected ade2 derivatives of CA12, termed CA12-1-R1 and CA12-1-R2, digested with EcoRV and probed with the cloned 2.2 kb KpnI–EcoRV fragment containing the C. albicans Ade2 gene (Methods). The genomic Southern analysis (Fig. 1) shows that a 2.7 kb EcoRV band, which contains the entire C. albicans Ade2 gene (Fig. 2a) (Kurtz et al., 1986), is present in CA11 and CA12 (Fig. 1, lanes 1 and 2), but is absent in the ade2 mutants CA12-1-R1 and CA12-1-R2 (lanes 3 and 4). A smaller band of 1.4 kb in size, is detected in CA12, CA12-1-R1 and CA12-1-R2 (lanes 2, 3 and 4), but not in CA11 (lane 1). These results suggested that CA12, in contrast to CA11, was heterozygous at Ade2, and that the ade2 derivatives of CA12 had lost Ade2 heterozygosity.

To determine the location of the deletion in the mutant ade2 allele in CA12, two PCR products of 2.2 and 0.9 kb in size were amplified using CA12 genomic DNA as a template and oligonucleotides P9 (corresponding to nucleotide position 9–33 of the Ade2 gene) and CR2244 (corresponding to nucleotide position 2221–2244 of the Ade2 gene) as primers (data not shown). The two primers were chosen as their PCR product covers almost the entire Ade2 gene (Fig. 2a). The 1.3 kb size difference between the two products matched exactly the size difference between the two homologous EcoRV bands displayed in the genomic Southern blot shown in Fig. 1. The two PCR products were cloned into pCRll and sequenced. The larger PCR product carried the wild-type gene Ade2, as its sequence is 99.60% identical (2239 out of 2248 bp) to that of Ade2 in C. albicans SC5314. The DNA sequence of the smaller PCR product was almost identical to that of Ade2 but contained a 1.3 kb deletion between positions 490 and 1764 of the Ade2 gene. The small PCR product was therefore determined to carry the null allele ade2. The 1.3 kb deletion spans the promoter and coding regions of the gene, between the two AATT repeats (Fig. 2b). Besides, the DNA sequence of ade2 differed from that of Ade2 by three transition mutations at the S′ promoter region: a C → T at position 281, a T → C at position 346 and an A → G at position 413. These sequence polymorphisms provided an additional way to distinguish the two alleles.

Adenine mutants are homozygous diploid at ade2

The loss of Ade2 heterozygosity in the ade2 mutants could be due to (1) de novo deletion of approximately 1.3 kb of the Ade2 gene; (2) haploidization; (3) aneuploidic loss of Ade2; or (4) homozygosis at ade2 (ade2/ade2) by mitotic recombination (Fig. 3). Using the PCR primers P9 and CR2244, ade2 alleles were amplified from three independent ade2 mutants of CA12, termed CA12-1-R1, CA12-1-R2 and CA12-1-R4, and cloned

![Fig. 1. Southern analysis of C. albicans CA12 and its adenine auxotrophic derivatives (lanes 1–4) and the prototrophic transformants of ade2 mutants (lanes 5–10). Lane 1, C. albicans CA11; lane 2, C. albicans CA12; lane 3, ade2 auxotroph CA12-1-R1 and lane 4, ade2 auxotroph C. albicans CA12-1-R2; lanes 5 and 6, CA12-1-R1 and its prototrophic transformant, CA12-1-R1-T1; lanes 7 and 8, CA12-1-R2 and its prototrophic transformant, CA12-1-R2-T1; lanes 9 and 10, CA12-2-R1 and its prototrophic transformant, CA12-2-R1-T1. Note the reappearance of the 2.7 kb EcoRV fragment in the transformants (lanes 6, 8 and 10). The fungal DNA was digested with EcoRV and probed with the 2.2 kb KpnI–EcoRV fragment that contains the entire C. albicans Ade2 gene.](image-url)
into pCRII. Two clones from each of the mutants were sequenced. The DNA sequences of the six clones were identical to each other and to that of ade2 of CA12 (data not shown), suggesting that none of the ade2 mutants was due to novel deletion of ADE2 and they all originated from the null ade2 allele in CA12.

PCR fragment P59-CR2244, corresponding to nucleotide position 59-2244 of the ADE2 gene, was amplified using primers P59 and CR2244, and was used to transform adenine auxotrophs CA12-1-R1 and CA12-1-R2. This PCR fragment is 2.2 kb in size and contains the missing 1.3 kb DNA sequence (Fig. 2a). The PCR fragment was introduced into the protoplasts of the recipient strains using the CaCl2-PEG method and the prototrophic transformants were selected on minimal medium free of adenine. One prototrophic transformant each was randomly chosen from the transformants of CA12-1-R1, CA12-1-R2 and CA12-2-R1, their DNA was extracted, digested with EcoRV and probed with the 2.2 kb ADE2 fragment. It is evident that the recipients CA12-1-R1, CA12-1-R2 and CA12-2-R1 (Fig. 1, lanes 5, 7 and 9) contain only the 1.4 kb fragment; while all of the three corresponding transformants CA12-1-R1-T1, CA12-1-R2-T1, and CA12-2-R1-T1 contain the 27 kb EcoRV fragment present in the parental CA12 cells (Fig. 1, lanes 6, 8 and 10), as well as the 1.4 kb fragment. The 1.4 kb fragment would be absent if these Ade* transformants were aneuploids containing only one copy of ade2. Our data can be best explained that the ade2 recipients contain two copies of ade2 and the transforming DNA has converted one of them to ADE2 by, presumably, homologous recombination. The restored ADE2 heterozygosity in the transformants was also confirmed; the three Ade* transformants were also prone to the generation of adenine mutants, as was their parental strain CA12, after UV irradiation (data not shown).

CA12-1-R1 and CA12-1-R2 were treated by UV mutagenesis and the surviving cells were transferred to adenine-supplemented minimal medium and YM medium by replica plating, to screen for additional auxotrophic mutants. We failed to detect any additional auxotrophs among the 3000 surviving cells screened. The detection of other auxotrophs was expected if these mutants were haploid cells (Fig. 3, path V). Based on the above data we conclude that the UV-induced adenine mutants are homozygous diploid at ade2.

**Both gene conversion and mitotic crossing over are responsible for the loss of ADE2 heterozygosity**

After UV irradiation, many of the Ade* derivatives of CA12 appeared as a red sector in an otherwise white colony, the white being composed of prototrophic cells. Two methods, UV mutagenesis and genomic Southern analysis, were used to examine the genotype of cells purified from the white sectors. Some of the cells derived from the white sectors such as CA12-1-W2 and CA12-2-W6 were no longer prone to the formation of Ade* mutants by UV irradiation (data not shown). Genomic Southern analysis demonstrated that CA12-1-W2 and CA12-2-W6 had lost ade2 and only contained ADE2.
Fig. 4. Southern analysis of the genotypes of the white sectors in the red/white twin-sectored colonies. Lanes 1 and 2, CA12-1-R1 and its sibling prototrophic white sector, CA12-1-W1; lanes 3 and 4, CA12-1-R2 and its sibling prototrophic white sector, CA12-1-W2; lanes 5 and 6, CA12-2-R1 and its sibling prototrophic white sector, CA12-2-W1; lanes 7 and 8, CA12-2-R6 and its sibling prototrophic white sector, CA12-2-W6. Southern analysis was done as described in Fig. 1.

**DISCUSSION**

In dissection of the genetic mechanism underlining natural fungal heterozygosity, *C. albicans* CA12 offers several experimental conveniences: (1) the red, adenine-requiring auxotrophic mutants are visually identifiable on media deficient in adenine; (2) the gene, *ADE2*, has a defined biochemical function, encoding phosphoribosyl-aminomimidazole carboxylase in the de novo purine biosynthetic pathway; (3) both integrative and self-replicating plasmid transformation systems are available for the rescue of *ade2* mutants (Kurtz et al., 1987; Cannon et al., 1992); (4) because of the presence of the large deletion at *ade2*, the wild-type and the defective allele are easily distinguishable by PCR or Southern analysis; and (5) the *ADE2* DNA sequence has been determined (Tsang et al., 1997).

We have demonstrated that the *ADE2* locus of *C. albicans* CA12 is heterozygous (i.e., *ADE2*/*ade2*). The null allele, *ade2*, has lost a 1.3-kb fragment in the promoter and coding regions of the gene as the result of a deletion between the two AATC repeats (Fig. 2). Our data clearly indicate that the natural heterozygosity at *ADE2* forms the genetic basis for the high frequency of the specific auxotrophic phenotype in *CA12* (Fig. 1), and that the loss of heterozygosity (LOH) at *ADE2* in *C. albicans* CA12 leads to the generation of *ade2* mutants (Fig. 1). This has, therefore, for the first time provided a molecular explanation for one of the puzzles in my-

---

**Fig. 3.** Five possible genetic rearrangements of *ADE2*/*ade2* heterozygotes. Path I refers to mitotic crossing over; path II, 3+:1m gene conversion, the non-reciprocal transfer of genetic materials; path III, 1+:3m gene conversion; path IV, aneuploidic loss of *ADE2*; and path V, haploidization. The sibling segregants are grouped together with the sign &. (-/ade2) refers to an *ade2* hemizygote. +, wild-type; m, mutant.
ology: how strain-specific, recessive mutants can be readily induced by UV or other mutagens in many natural isolates of the diploid organism *C. albicans*.

We have also revealed that the ade2 derivatives of CA12 are diploid cells homozygous at ade2 (Fig. 1) and the homozygosis is caused by UV-induced mitotic recombination. Mitotic recombination can lead to either reciprocal (mitotic crossing over) or non-reciprocal (gene conversion) transfer of genetic material (Fig. 3, paths I, II and III). We had previously suggested that gene conversion is one of the mechanisms for the generation of adenine mutants in *C. krusei* (Cao et al., 1997). In the present study, our genetic analysis of the white prototrophic sectors in the red/white sectored colonies has furnished revealing information on the pathways of mitotic recombination. Two classes of the white prototrophic sectors were detected. The first class, which was previously called mitotically stable prototrophic strains (Poulter et al., 1981), were no longer able to further segregate to give ade2 auxotrophs and were homozygous at the ade2 locus. This type of red/white sectored colony is most likely the consequence of the mitotic crossing over (Fig. 3, path I). The second class of the white prototrophic sectors occurred more often. They remained prone to produce UV-induced ade2 mutants and were heterozygous at ADE2 (Fig. 3, path III). These white sectors were certainly not due to contamination of un-mutagenized cells grown next to the sectored colonies as we failed to detect the existence of the mixed population of ADE2/ade2 and ADE2/ade2 in more than 30 white sectors examined (data not shown). We therefore conclude the existence of two pathways of mitotic recombination in *C. albicans* CA12: crossing over and gene conversion.

Our data support the basic tenets of the natural heterozygosity hypothesis (Whelan et al., 1980) and furthermore indicate, based upon the frequent occurrence of 1 : 1m segregation of *ADE2*, that gene conversion may play an important role in the LOH of ADE2. The actual contribution of gene conversion to the mitotic recombination is likely to be underestimated since the current investigation does not include the 3 : 1m gene conversion of ADE2. Both of the reciprocal genotypes of the 3 : 1m gene conversion are white prototrophic cells, but one with a genotype of ADE2/ade2 and the other ADE2/ade2 (Fig. 3, path II). In addition, the method we used for the detection of ADE2/ade2 heterozygotes, i.e. screening the red colonies after UV mutagenesis, was not a sensitive one and may have missed some of the mutants.

The frequency of LOH of the ADE2 under natural conditions is unknown but is expected to be low, for we did not detect any spontaneous red adenine mutants from CA12 in the absence of UV treatment. It remains to be examined whether any other chemical or physical agents may promote the LOH more efficiently than UV irradiation; or whether LOH of some genes may lead to the generation of mutants that are favourably selected under certain living environments. We have noticed that the 1.3-kb deletion occurs between two AATC repeats (Fig. 2). It would be unwise to simply ignore the phenomenon as a fortuitous event, but it is equally difficult to argue that the AATC repeats provide sufficient cis-acting information for site-specific recombination, as numerous copies of the tetranucleotide are interspersed throughout the *C. albicans* genome. Additional experiments are required to prove or disprove the significance of the phenomenon.

*C. albicans*, like numerous other imperfect fungi, is an obligate diploid organism. Many evolutionary advantages such as biodiversity and hybrid vigour granted by meiosis are denied to these fungi. It has long been suggested that *C. albicans* relies upon certain unique genetic processes, such as heritable phenotypic variation (also called phenotypic instability or switching) associated with colony morphology (Sultan et al., 1985) and ploidy change (Suzuki et al., 1982; Janbon et al., 1998); to compensate for its intrinsic genetic deficiency. The frequent deletion of *C. albicans* natural isolates with a wide spectrum of recessive heterozygosity (Poulter, 1987) may be an unfortunate consequence of the absence of meiosis in the fungus, as mitotic recombination is a much slower process of removing mutant alleles. Alternatively, the natural heterozygosity may serve as yet another vehicle by the organism to elevate its genetic variability. It will be interesting and worthwhile to test the competitiveness of strains heterozygous at ADE2 over their corresponding isogenic strains homozygous at the locus. It is our hope that the full comprehension of the phenomenon of fungal natural heterozygosity does not just satisfy academic curiosity, but also provides useful information that may guide *C. albicans* geneticists to design alternative approaches to create desired mutations in this obligate diploid.

**ACKNOWLEDGEMENTS**

P. W. K. Tsang and B. Cao contributed equally to this work. We thank Drs D. Tsang and L. P. Samaranayake for *C. albicans* strains; Dr R. D. Cannon for plasmids pRC2231 and pSC17; *C. albicans* strains hOG24 and hOG300; Dr C. B. Hazlett for helpful comments; Dr D. C. Coleman and two anonymous referees for constructive criticisms and the University Grants Committee of the Hong Kong Special Administrative Region of PRC for financial support.
