Adherence of Mycoplasma pneumoniae to host cells requires several mycoplasmal membrane proteins and cytoskeleton-like proteins in addition to the adhesin P1, a transmembrane protein of 170 kDa. To analyse interactions of the P1 adhesin with other membrane proteins or with cytoskeleton-like proteins, cross-linking studies were performed in vivo using the permeant reagent paraformaldehyde. The cross-linked protein complex was isolated by immunoaffinity chromatography, and proteins complexed to the P1 protein were identified by immunoblot analysis followed by high mass accuracy tryptic peptide mapping using matrix-assisted laser desorption/ionization mass spectrometry (MALDI MS). In addition to the P1 protein and a truncated form of the same protein, the adhesin-related 30 kDa protein, two membrane proteins of 40 and 90 kDa, the cytoskeleton-associated 65 kDa protein and two cytoskeleton-forming proteins, HMW1 and HMW3, were found to be components of the isolated protein complex. Furthermore, the cross-linked complex contained the chaperone DnaK and the E1α subunit of pyruvate dehydrogenase. In summary, it was shown that cytadherence-associated membrane proteins are located in close proximity to cytoskeleton-like proteins, suggesting a functional interaction between membrane and cytoskeleton-like proteins. DnaK might be involved in translocation of proteins from the cytoplasm to the membrane and pyruvate dehydrogenase might be a structural protein of the attachment organelle.

Keywords: Mycoplasma pneumoniae, P1 adhesin, paraformaldehyde cross-linking

INTRODUCTION

Mycoplasma pneumoniae is an obligate parasitic bacterium of the human respiratory tract which causes tracheobronchitis or atypical pneumonia (Baseman & Tully, 1997; Taylor-Robinson, 1996). Attachment to the respiratory epithelium is the first step in the infection process. Adherence of M. pneumoniae to its host cell is a complex event which requires a terminal structure (attachment organelle) at one pole of the bacterial cell which mediates the interaction of the bacteria with the host (Baseman et al., 1982, 1996; Razin et al., 1998). The function of the attachment organelle depends on the proper arrangement and interaction of several membrane proteins with cytoskeleton-forming proteins which stabilize the terminal structure (Krause, 1996, 1998; Meng & Pfister, 1980).

Adhesin P1 of M. pneumoniae, a transmembrane protein with a molecular mass of 170 kDa, as well as the adhesin-related 30 kDa protein and the two cytadherence-associated proteins of 40 and 90 kDa cluster densely in the membrane of the attachment organelle (Dallo et al., 1990; Feldner et al., 1982; Franzoso et al., 1993; Layh-Schmitt & Herrmann, 1992, 1994). The high density and close proximity of these proteins in the terminal structure seem to be prerequisite for effective cytadherence. The two accessory proteins of 40 and 90 kDa are post-translational cleavage frag-
ments of the ORF6 gene product, which is encoded by an ORF of the P1 operon next to the P1 gene (Inamine et al., 1988; Sperker et al., 1991). Previous cross-linking studies with a non-permeant cross-linking reagent showed that the ORF6 gene products are located on the bacterial cell surface in close proximity to the P1 protein (Layh-Schmitt & Herrmann, 1994).

Some of the ORF6 gene products and the P1 molecules are retained by the Triton-X-100-insoluble fraction of the M. pneumoniae cells, which apparently represents a filamentous structure composed of numerous proteins and resembling the eukaryotic cytoskeleton (Kahane et al., 1985). However, the lack of the ORF6 gene product in a spontaneous haemadsorption-negative mutant resulted in the release of all the P1 protein into the Triton-soluble phase (Layh-Schmitt & Harkenthal, 1999). These findings suggest that the ORF6 gene product may be responsible for proper disposition of the P1 molecules in the mycoplasma membrane, which seems to be a prerequisite for interaction of the 40 and 90 kDa cytadherence-associated proteins and the P1 protein with the cytoskeleton. As suggested by Krause (1996, 1998) and Hahn et al. (1998), the cytoskeleton-forming proteins might play a scaffolding role in locating the P1 molecule in the membrane of the tip structure. Some components of the mycoplasma cytoskeleton have been well characterized: the cytoskeleton-forming, high-molecular-mass-proteins HMW1, 2 and 3 (Krause, 1996, 1997) and the cytoskeleton-forming proteins (HMW1, 2 and resembling the eukaryotic cytoskeleton (Kahane et al., 1985).

For this reason, in the present study, we focused on the determination of proteins which are located within the cell membrane or inside the cell in close proximity to the transmembrane protein P1. Hence, cross-linking studies using the permeant cross-linking reagent paraformaldehyde were carried out. The proteins linked to the P1 molecules were analysed by immunoblot analysis and matrix-assisted laser desorption/ionization mass spectrometry (MALDI MS).

METHODS

Bacterial strain, culture conditions and harvesting. Mycoplasma pneumoniae M129 (ATCC 29342) was cultured in modified Hayflick medium for 48 h at 37°C in 75 cm² cell culture flasks (Greiner) (Hayflick, 1965). Before harvesting, the culture medium was discarded and the adherent bacteria were scraped off the culture flasks into fresh culture medium, pelleted for 15 min at 6000 g at 4°C, and then washed twice with PBS (0.14 M NaCl; 0.01 M sodium phosphate buffer, pH 7.4).

Antiserum. Rabbit antiserum against the P1 protein (Proft & Herrmann, 1994), the 90 and 40 kDa proteins (Layh-Schmitt & Herrmann, 1992), the 30 kDa protein (Layh-Schmitt et al., 1995, 1997) and the cytoskeleton-forming proteins (HMW1, HMW3 and P65) (Proft & Herrmann, 1994; Proft et al., 1995) were produced as described previously.

In vivo cross-linking by paraformaldehyde. Cross-linking studies were performed according to the method described by Skare et al. (1992). To evaluate the appropriate cross-linking conditions bacterial suspensions were incubated with 1% paraformaldehyde (Merck) in PBS, pH 6.5 [30 mg cells (wet weight) ml⁻¹], at room temperature for different lengths of time (10, 20, 30, 40, 50, 60 and 75 min). Two hundred microlitre samples of the incubation mixture were transferred into microfuge tubes containing 500 µL PBS, pH 6.5. The cross-linking reaction was stopped by centrifuging the cells from the paraformaldehyde solution at 6000 g for 15 min. The bacteria were washed twice with PBS, and the pellets were finally resuspended in 50 µL 2× Laemmlı buffer (Laemmli, 1970). Prior to SDS-PAGE and immunoblot analysis, the cells were lysed by incubation at 60°C for 10 min or heated to 95°C for 15 min to break the cross-links.

To enrich cross-linked complexes, 200 mg (wet weight) M. pneumoniae cells was treated with 7 ml 1% paraformaldehyde in PBS for 60 min. Cross-linking was stopped by centrifugation of the cells at 6000 g for 10 min. The pellet was washed with PBS three times and frozen at −20°C until needed for immunoaffinity chromatography.

Preparation of the immunoaffinity chromatography column. A bed volume of 1 ml Sepharyl-protein A (Pierce) with a binding capacity of 15 mg human IgG was loaded in a 15 ml plastic column (Bio-Rad). The gel material was washed with 10 vols IgG-binding buffer (Pierce). One millilitre of rabbit antiserum against the P1 protein was added to the column. The gel was incubated overnight at 4°C by gentle shaking in a rotating shaker. Unbound protein was released from the gel by washing with 10 vols IgG-binding buffer (Pierce). IgG was covalently bound to the protein A matrix by adding 2 ml of the cross-linking reagent dimethyl pimelimidate (Pierce) to a final concentration of 20 mM in 200 mM sodium borate buffer, pH 9.0. After 1 h incubation at room temperature the gel was washed with 5 ml 200 mM borate buffer, pH 9.0, and then the excess reactive groups of the cross-linking reagent were blocked with 2 ml ethanolamine (200 mM, pH 8.0) during incubation for 10 min. IgG molecules which were not covalently bound to protein A were released from the gel matrix by 5 ml 0.2 M glycine/HCl, pH 2.8. Thereafter the gel was washed twice with 10 ml IgG-binding buffer.

Imunoaffinity chromatography for isolating cross-linked protein complexes. The paraformaldehyde-treated bacteria (200 mg wet weight) were lysed in 800 µl lysis buffer (2% SDS, 25 mM NaCl, 25 mM Tris/HCl (pH 7.2) and 10 U aprotinin (Sigma) ml⁻¹), heated to 60°C for 5 min, and then diluted in 4 vols (3-2 ml) dilution buffer [2.5% Triton X-100 (Pierce), 190 mM NaCl, 60 mM Tris/HCl, 10 U aprotinin ml⁻¹]. The lysate was mixed with the antibody-bound gel material in a 15 ml column. The column was closed with a plastic cap and the gel was incubated with the lysate by gentle shaking with an overhead shaker overnight at 4°C. The protein A matrix with the bound antibody–antigen complex was washed four times with 10 ml washing buffer I [0.1% Triton X-100, 0.02% SDS, 150 mM NaCl, 50 mM Tris/HCl (pH 7.5), 5 mM EDTA] and twice with washing buffer II [150 mM NaCl, 50 mM Tris/HCl (pH 7.5), 5 mM EDTA]. Cross-linked protein complexes containing the P1 protein were eluted from the gel with 2 ml 3.5 M KSCN. After dialysis against 3 mM Tris/HCl buffer...
mycoplasma cells with paraformaldehyde (Figs 1 and 2). Under the same conditions the 30 and 40 kDa proteins were only partially cross-linked (Figs 1 and 2). Even after cross-linking for 2 h no additional decrease in the intensity of the 30 and 40 kDa protein bands was observed (not shown).

The cross-linked proteins formed high-molecular-mass protein complexes which could not be separated by SDS-PAGE. Non-penetrating material was detected on the top of the stacking gel and in the interface between the stacking and separating gel by immunoblotting (Figs 1 and 2). The integrity of the individual proteins in the cell pellets of 200 µl M. pneumoniae suspensions [30 mg cells (wet weight) ml−1] which were incubated with paraformaldehyde for different lengths of time were lysed in 50 µl 2× Laemmli buffer at 60 °C for 5 min. To break the cross-links the samples were incubated at 95 °C for 15 min.

**RESULTS**

**Cross-linking by paraformaldehyde**

*M. pneumoniae* cells were incubated with 1% paraformaldehyde for different lengths of time in order to determine the optimal reaction conditions (Fig. 1). Immunoblot analysis revealed that protein bands derived from cytoskeleton-forming or cytoskeleton-associated proteins such as HMW1 (apparent molecular mass 205 kDa), HMW3 (apparent molecular mass 130 kDa) and P65, as well as from the membrane proteins P1 (170 kDa) and the 90 kDa protein, disappeared totally after 60 min incubation of intact cell pellets with 1% paraformaldehyde for 10 min (lanes 2 and 8), 20 min (lanes 3 and 9), 40 min (lanes 4 and 10), 50 min (lanes 5 and 11) and 60 min (lanes 6 and 12). In lanes 8–12, protein cross-links of paraformaldehyde-treated cells were broken by heat. The immunoblot was probed with antisera against HMW1, P1, P90, P40 and P30.

**S DS-PAGE and immunoblot analysis.** Cell pellets of 200 µl M. pneumoniae suspensions [30 mg cells (wet weight) ml−1] which were incubated with paraformaldehyde for different lengths of time were lysed in 50 µl 2× Laemmli buffer at 60 °C for 5 min. To break the cross-links the samples were incubated at 95 °C for 15 min. Five microlitres of each sample was separated by 10% SDS-PAGE (Laemmli, 1970) before and after breaking the cross-links. The same procedure was used for resolving cross-linked protein complexes eluted from immunoaffinity chromatography columns. Immunoblotting was carried out as described previously (Layh-Schmitt & Herrmann, 1992, 1994) according to the method of Towbin et al. (1979). Antibodies against the P1 protein, the 30, 40 and 90 kDa proteins, and P65 were diluted 1:1000. Antibodies against HMW1, HMW3 and DnaK were diluted 1:5000.

**Identification of proteins by MALDI MS.** The determination of peptide masses by MALDI MS in combination with database searching is an excellent method of identifying proteins of an organism if the corresponding DNA or protein sequences are stored in the database. Since the complete genome sequence of *M. pneumoniae* is known (Himmelreich et al., 1996), we initiated analysis of the mass of tryptic fragments of proteins complexed to the P1 adhesin by MALDI MS.

After breaking the cross-links, individual proteins of the affinity-chromatography-purified protein complex were separated by 10% SDS-PAGE. The bands of interest were excised from the gel, washed, reduced in the gel, S-alkylated, and subjected to proteolytic digestion with an excess of sequence grade trypsin (Boehringer Mannheim) as described previously (Shevchenko et al., 1996). After 3 h digestion, 0.3 µl digestion supernatant was removed and deposited directly into an acidified water droplet placed on the top of the matrix surface. A mixture of a saturated solution of α-cyano-hydroxycinnamic acid (Sigma) and nitrocellulose in acetone (Bio-Rad) was used as a ‘fast evaporation’ matrix. Peptide mass maps were recorded on a Bruker Reflex Matrix-Assisted Laser Desorption Ionization Time-of-Flight mass spectrometer (Bruker-Franzen). All of the spectra were obtained as 100-shot means. Tryptic autolysis peaks and some matrix-related peaks were used for internal calibration. Proteins were identified using Peptide Search software to search a set of tryptic peptide masses against a non-redundant protein sequence database (NRDB) (Mann & Wilm, 1994). Mass accuracy was better then 50 p.p.m.
cross-linked complexes was established by heating the lysates of paraformaldehyde-treated mycoplasmas to 95 °C for 15 min. Subsequent SDS-PAGE and immunoblotting with specific antibodies revealed the individual membrane and cytoskeleton proteins (Figs 1 and 2).

Based on these results paraformaldehyde cross-linking of proteins associated with or located in close proximity to P1 was carried out for 60 min (Fig. 2).

**Immunoblot analysis of proteins cross-linked to P1**

Individual proteins of the protein complexes isolated by affinity chromatography were released by breaking paraformaldehyde cross-links at 95 °C for 15 min. The proteins were resolved by SDS-PAGE. Immunoblot analysis revealed the proteins complexed to the P1 protein. The P1 protein complex contained the P1 protein, the 90 and 40 kDa proteins, the adhesin-related 30 kDa protein, DnaK, the cytoskeleton-forming proteins HMW1 and HMW3 and the cytoskeleton-associated 65 kDa protein. The HMW proteins were detected in minute amounts, indicating that only a small proportion of the cytoskeleton-forming proteins was associated with the P1 protein complex (Fig. 3). When lysates of untreated *M. pneumoniae* cells were used for immunoaffinity chromatography only the P1 protein was purified (not shown). This indicated that proteins which were co-purified with the P1 protein were specifically cross-linked to each other by paraformaldehyde.

**MALDI MS analysis of proteins cross-linked to P1**

Proteins complexed to P1 in paraformaldehyde-treated *M. pneumoniae* cells were isolated by immunoaffinity chromatography. Before and after breaking cross-links the proteins were separated by SDS-PAGE (Fig. 4). A small proportion of the P1 protein could not be cross-linked, as shown in Fig. 4, lane 2. The protein bands (Fig. 4, lane 3) were cut out of the Coomassie-stained gel and treated with trypsin.

The molecular masses of tryptic fragments of proteins cross-linked to the P1 protein were analysed by high-accuracy MALDI MS. The resulting peptide mass maps were used to search sequence databases. Thus the P1 protein, the 90 kDa protein, DnaK, C-terminal truncated forms of DnaK and of the P1 protein, and the E1α subunit of the pyruvate dehydrogenase complex were identified as components of the cross-linked complex by MALDI MS (Fig. 4). An example of the mass spectrum of tryptic fragments of the P1 protein is shown in Fig. 5. The 30 kDa protein seen on the SDS-PAGE gel (Fig. 4) could not be identified but it can be assumed that this band is the adhesin-related 30 kDa protein of *M. pneumoniae*, as immunoblot analysis revealed the presence of this protein in the cross-linked complex (Fig. 3). With the exception of the pyruvate dehydrogenase E1α subunit, all proteins detected by MALDI MS could also be identified by immunoblot analysis. Since antibodies against pyruvate dehydrogenase were not available, the presence of this protein in the cross-linked protein complex could not be confirmed by immunoblot analysis.
DISCUSSION

Biochemical, genetic, immunological and electron microscopic studies over the last 10–15 years have established a comprehensive picture of the individual proteins involved in *M. pneumoniae* cytadherence and of their localization in the cell (Krause, 1998; Razin *et al*., 1998). The results indicate that clustering of the P1 adhesin together with the adhesin-related 30 kDa protein and the cytadherence accessory proteins of 40 and 90 kDa in the membrane of the characteristic terminal structure of the cell is essential for effective attachment of *M. pneumoniae* to its host cell. The 40 and 90 kDa proteins and the cytoskeleton-forming proteins HMW1–HMW3 are required for tip structure formation and clustering of the P1 protein in the tip, as spontaneous cytadherence-negative mutants lacking the 40 and 90 kDa protein or HMW1–HMW3 exhibit a round or ovoid morphology without a distinct terminal organelle (Baseman *et al*., 1982; Hahn *et al*., 1998; Layh-Schmitt *et al*., 1995; Layh-Schmitt & Harkenthal, 1999). Moreover, these mutations resulted in a random distribution of the P1 protein in the mycoplasma cell membranes, suggesting an intimate interaction of the P1 protein, not only with the 40 and 90 kDa proteins, but also with one or more of the HMW1–HMW3 proteins.

To expand our knowledge of the interactions between cytadherence-associated membrane proteins (P1 adhesin, 90, 40 and 30 kDa proteins) and cytoplasmic proteins of the mycoplasma cell, we performed nearest-neighbour analyses using the permeant cross-linking reagent paraformaldehyde. In comparison to other chemical cross-linkers paraformaldehyde has the advantage of being non-specific with respect to its reaction partner and applicable for *in vivo* use. Cross-linking by paraformaldehyde is reversible by heat (95 °C). Therefore, individual proteins of paraformaldehyde cross-linked complexes can be analysed after breaking the cross-links. Furthermore, paraformaldehyde is a monomer in solutions, and therefore cross-linking of proteins by this reagent requires close associations. Since paraformaldehyde is able to permeate the cell membrane, cross-linking of proteins can occur inside the membrane or the bacterial cell as well as on the cell surface.

In this study we focused on the identification of individual proteins complexed to the P1 protein by paraformaldehyde by the use of a combination of two different methods: immunoblot analysis and MALDI MS.

We screened a series of defined antisera for their reactivity with particular proteins of the isolated protein complex. We were able to identify the membrane proteins of 90 kDa and 40 kDa (ORF6 gene product), the 30 kDa adhesin-related protein, the cytoskeleton-associated protein of 65 kDa, and minute amounts of the cytoskeleton-forming proteins HMW1 and HMW3, in addition to the P1 protein. The results achieved with nearest-neighbour analysis using the permeant cross-linker paraformaldehyde provided unequivocal proof of direct associations of the P1 protein and/or other cytadherence-associated membrane proteins (30, 40 and 90 kDa proteins) with defined cytoskeleton proteins. Since cross-linking of the P1 protein (and/or the 90 and 40 kDa proteins) with the 30 kDa protein, the HMW proteins and the 65 kDa protein was achieved with the permeant reagent paraformaldehyde but not with the impermeant cross-linking reagent DTSSP (Layh-Schmitt & Herrmann, 1994), we suggest that interactions between these proteins occur via their transmembrane or cytoplasmic regions. Furthermore, cross-linking with DTSSP is restricted to reactive amino groups whereas reactivity of paraformaldehyde is less specific and might result in a higher number of cross-linked proteins. Several of the proteins detected in the cross-linked complex (P1, the 30 and 90 kDa proteins, P65 and the HMW1 and HMW3 proteins) contain proline-rich repeat regions which might play a role in protein–
protein interactions. For a considerable number of eukaryotic membrane proteins homologous or hetero-
logous interactions have been shown to be a common feature, with the transmembrane segments the principal
sites of interaction (Brosig & Langosch, 1998; Langosch & Herrlinga, 1998).

The use of MS for the characterization of functional protein complexes has been described previously
(Neubauer et al., 1997). Here we show that the same technology can be applied to determine which proteins
of the mycoplasma membrane or cytoplasm are located in close proximity to each other to form complexes after
cross-linking. By using MALDI MS we were able to confirm the results obtained by immunoblot analysis
and to identify two additional proteins which were components of the P1 complex—namely DnaK and the
E1α subunit of pyruvate dehydrogenase.

DnaK may play a role in translocating membrane proteins from the cytoplasm into the cell membrane,
resulting in an association of DnaK with the P1 protein or other membrane proteins. Such an association of
DnaK with the membrane has been shown previously for Escherichia coli (Bukau et al., 1993). It is still unclear
whether the truncated forms of DnaK and P1 detected in the cross-linked complex were an experimental artefact
or whether these proteins are naturally expressed in variable forms. The pyruvate dehydrogenase complex
has been shown to be located in the membrane of Acroleplasma laidlawii, which, like M. pneumoniae, is
a member of the Mollicutes (Wallbrandt et al., 1992). Therefore, in M. pneumoniae pyruvate dehydrogenase
might also be associated with the membrane, leading to cross-linking with the isolated protein complex. Alterna-
tively, the pyruvate dehydrogenase E1α subunit might function as a structural protein essential for the assembly
and/or regulation of cytadherence-associated proteins which were detected in the cross-linked complex. This
assumption is supported by the findings of Spellerberg et al. (1996), who proposed a role for a member of the
pyruvate oxidase family in the regulation of adhesive properties and virulence of Streptococcus pneumoniae.

The data presented in this paper provide insights into the interactions between the membrane and cytoskeletal
proteins of M. pneumoniae. Further biochemical studies are needed to define the regions of individual proteins
essential for the mycoplasma protein–protein interactions in the attachment organelle of M. pneumoniae.
The mycoplasma cell might serve as a model prokaryotic organism for studying protein–protein interactions as
well as structure–function relationships because its complete genome sequence is known, the number of genes and proteins (approx. 600) is relatively low, and its architecture (lack of cell wall) is simple.

ACKNOWLEDGEMENTS

We would like to thank Professor H.-G. Sonntag, Hygiene-Institut Heidelberg, for supporting this work and Professor R.
Herrmann for providing antisera. The study was funded by the Deutsche Forschungsgemeinschaft He-780/7-2.
