Intracellular pH regulation by *Mycobacterium smegmatis* and *Mycobacterium bovis* BCG

Min Rao, Trevor L. Streur, Frank E. Aldwell and Gregory M. Cook

INTRODUCTION

*Mycobacterium tuberculosis*, the principal agent of tuberculosis (TB) in humans causes approximately three million deaths per year and it is estimated that up to one third of the world’s population has been exposed to TB. Increased susceptibility of HIV-infected individuals and the emergence of multidrug-resistant strains make TB the leading cause of disease by an infectious agent (Bloom & Murray, 1992). Effective new TB control and prevention strategies will require additional knowledge of the growth mechanisms of *M. tuberculosis*. In this study, *Mycobacterium smegmatis* and *Mycobacterium bovis* [Bacille Calmette–Guérin (BCG)] were used as examples of fast- and slow-growing mycobacteria, respectively, to study biochemical and physiological responses to acidic pH. *M. smegmatis* and *M. bovis* BCG were able to grow at pH values of 4.5 and 5.0, respectively, suggesting the ability to regulate internal pH. Both species of mycobacteria maintained their internal pH between pH 6.1 and 7.2 when exposed to decreasing external pH and the maximum ΔpH observed was approximately 2.1 to 2.3 units for both bacteria. The ΔpH of *M. smegmatis* at external pH 5.0 was dissipated by protonophores (e.g. carbonyl cyanide m-chlorophenylhydrazone), ionophores (e.g. monensin and nigericin) and *N*,*N*-dicyclohexylcarbodiimide (DCCD), an inhibitor of the proton-translocating F1F0-ATPase. These results demonstrate that permeability of the cytoplasmic membrane to protons and proton extrusion by the F1F0-ATPase plays a key role in maintaining internal pH near neutral. Correlations between measured internal pH and cell viability indicated that the lethal internal pH for both strains of mycobacteria was less than pH 6.0. Compounds that decreased internal pH caused a rapid decrease in cell survival at acidic pH, but not at neutral pH. These data indicate that both strains of mycobacteria exhibit intracellular pH homeostasis and this was crucial for the survival of these bacteria at acidic pH values.

**Keywords:** pH regulation, mycobacteria, membrane potential, proton ATPase
unrestricted manner indicating that *M. tuberculosis* was unique among the mycobacteria in its extreme sensitivity to acid (Chapman & Bernard, 1962). Portaels & Pattyn (1982) reported that *Mycobacterium smegmatis* was capable of growth over a wide pH range with optimum growth observed between pH 5.0 and 7.4, and partial growth at pH 4.6. A more recent study by O'Brien et al. (1996) has demonstrated that exposure of *M. smegmatis* to sublethal, adaptive acidic pH (e.g. pH 3.0) conferred a significant level of protection against subsequent exposure to lethal pH (e.g. pH 3.0) compared to unadapted cells grown at pH 7.6, but no mechanism for this acid-tolerant response was provided. In contrast to other micro-organisms that exhibit an acid-tolerant response or acid habituation, the magnitude of protection was only a two- to threefold increase in cell viability for *M. smegmatis* compared to adapted cells of *Salmonella typhimurium* which are 100 to 1000 times more resistant to strong acid challenge (e.g. pH 3.3) compared to unadapted cells (Foster & Hall, 1990).

Due to the paucity of basic information that exists on how mycobacteria cope with acidic pH and pH in general, we have studied the effect of external pH on intracellular pH homeostasis in *M. smegmatis* and *Mycobacterium bovis* BCG. The results reported in this communication demonstrate that both species of mycobacteria adopt intracellular pH homeostasis and this was essential for survival at acidic pH.

**METHODS**

**Chemicals and radiochemicals.** CCCP (carbonyl cyanide m-chlorophenylhydrazone), DCCD (N,N'-dicyclohexylcarbodiimide), monensin, valinomycin and nigericin were obtained from Sigma. [Carboxyl-14C]salicylic acid (56 mCi mmol−1) was obtained from ICN Biomedicals. The following radiochemicals were obtained from NEN: [3H]methyltriphenylbenzoate (TPP) (30–60 Ci mmol−1), [7–14C]benzoic acid (10–25 Ci mmol−1), [1,2-3H]taurine (5–30 Ci mmol−1) and [3H]water (25 Ci mmol−1).

**Growth and maintenance.** Cultures of *M. smegmatis* mc²155 (Snapper et al., 1990) and *M. bovis* BCG (Pasteur 1173P2) were used in this study. For liquid culture, cells were grown with gentle agitation at 37 °C in supplemented Middlebrook 7H9 broth (Difco Laboratories) containing sterile Middlebrook ADC enrichment (Becton Dickinson) and 0.05% Tween 80 (Sigma). For solid medium, supplemented Middlebrook 7H11 (1.5% agar) with OADC (Becton Dickinson) and glycerol (0.5%, v/v) was used. All cells used as inocula were washed in saline (0.85% NaCl). To acclimatize supplemented and non-supplemented 7H9 medium, the pH was adjusted with 2 M HCl. Culture optical density was measured with a Beckman DU-64 spectrophotometer at 600 nm (OD600) using culture samples diluted with saline to bring the OD600 to below 0.7 when measured in cells of 1 cm light path length.

**Protonmotive force (Δp) measurements.** Mid-exponential phase cultures were harvested by centrifugation (8000 g, 15 min, 10 °C) and washed in 100 mM sodium citrate/phosphate buffer (pH 7.0). Cells were resuspended to a final OD600 of 1.0 in a volume of 2 ml (glass tubes). Where the external pH was varied (pH 4.0 to 7.0), initial experiments were carried out using non-supplemented 7H9 medium, but there was no detectable difference in ΔpH values between using this medium and one of the following buffers: 100 mM sodium citrate/phosphate buffer, 100 mM potassium- and sodium-phosphate buffer at the external pH being studied. Citrate/phosphate buffer has been used extensively for measuring internal pH and acid survival in other bacteria (Baronofsky et al., 1984; Terracciano & Kashket, 1986; McGowan et al., 1998) and this was the buffer routinely used in this study. Cells were energized with 20 mM glucose for 15 min followed by the addition of [14C]caffeine (0.5 µM final concentration), [7–14C]benzoate (11 µM, pK 4.2) or [14C]salicylic acid (10 µM, pK 3.0) at pH values below 5.0. [1,2-3H]taurine (50 µM) and H2O (25 mM) were used to determine intracellular volume. Taurine has been shown to be non-metabolizable by *M. tuberculosis* (Zhang et al., 1999) and this was confirmed for the mycobacteria used in this study. After incubation for 10 min at 37 °C, the cultures were centrifuged through 0.5 ml silicon oil (BDH Laboratory Supplies) in 1 ml microcentrifuge tubes (13000 g, 5 min, 22 °C) and 20 µl samples of supernatant were removed. The tubes and contents were frozen (−20 °C) and cell pellets were dissolved in scintillation fluid and counted. The silicon oil mix used in this study was a 40% mixture of phthalic acid bis(2-ethylhexyl ester) and 60% silicone oil (40% part mixture of DC200/200 silicone oil and 60% DC 550). Silicone oils were left overnight at room temperature to equilibrate.

The intracellular volume ([3.45 ± 0.59 µl (mg protein)−1] was estimated from the difference between the partitioning of [14C]taurine. The electrical potential across the cell membrane (membrane potential; ΔΨ) was calculated from the uptake of [3H]TPP according to the Nerst relationship. Non-specific TPP binding was estimated from cells which had been treated with valinomycin and nigericin (10 µM each) for 25 min. These inhibitors have been used previously with *M. smegmatis* (De Rossi et al., 1998; Choudhari et al., 1999). The ΔpH was determined from the distribution of [14C]-benzoate or [14C]salicylic acid using the Henderson–Hasselbalch equation (Reibeling et al., 1975) and ZαpH was calculated as 62 mV × ΔpH.

**Determination of lethal internal pH for *M. smegmatis* and *M. bovis* BCG.** The determination of lethal internal pH for *M. smegmatis* and *M. bovis* BCG was as reported by Foster & Hall (1991). Mycobacteria were grown to the exponential phase (OD600 0.5–1.0) in supplemented 7H9 broths (pH 7.0) and harvested by centrifugation (8000 g, 15 min, 10 °C). Cells were resuspended in non-supplemented 7H9 medium and 20 mM glucose at pH 5.0 or 5.5. Preliminary experiments indicated that 20 min exposure to 500 µM CCCP prior to the measurement of intracellular pH was required to reduce the internal pH from 6.7 to 5.5, but CCCP did not eliminate ΔpH completely. An exposure time of 4 h to 250 µM CCCP at pH 5.0 was required to cause a 68% decline in viability of *M. smegmatis*; this was the time chosen for cell-survival experiments. To reduce the level of CCCP associated with the cells prior to plating, cell suspensions were harvested by centrifugation (13000 g, 5 min, 22 °C) and washed twice in 1 ml sterile 0.9% NaCl. Cell viability (survival) was determined as the number of bacteria remaining as a percentage of the starting count. All samples were diluted in sterile saline (pH 7.0) and three 100 µl volumes of each dilution (10−4 to 10−6) were spread plated on 7H11 agar plates in duplicate. Cell viability, as measured by c.f.u., was determined after 2–3 days for *M. smegmatis* and 2–3 weeks for *M. bovis* BCG, or after colonies were visible at 37 °C. The minimum detection limit was 100 c.f.u. ml−1. The results are expressed as log percentage.
survival and represent the mean values of two independent experiments.

Measurement of oxygen consumption by washed cell suspensions, and other analyses. For oxygen consumption measurements, cells were harvested from exponentially growing cultures (OD$_{600}$ ~ 0.5) by centrifugation (8000 g, 15 min, 10°C), washed in 100 mM sodium citrate/phosphate buffer (pH 7.0) and resuspended in the same buffer to give protein concentrations of 5–10 mg protein ml$^{-1}$. Respiration rates were measured in a Rank Bros Clark-type oxygen electrode at 37°C as described by Carneiro de Melo et al. (1996). Glucose (20 mM) was added as an oxidizable carbon source. The oxygen electrode was calibrated with air-saturated sodium citrate/phosphate buffer (220 nmol dissolved O$_2$ ml$^{-1}$ at 37°C). Protein from NaOH-hydrolysed cells (0.2 M NaOH, 100°C, 20 min) and cell membranes was assayed by the method of Markwell et al. (1978).

Preparation of bacterial cell membranes and ATPase assays. Cell membranes of M. smegmatis were prepared as previously described (Basu et al., 1992). Membrane-bound ATPase activity was determined in triplicate by the colourimetric assay of inorganic phosphate liberated from ATP hydrolysis as described by Kobayashi & Anraku (1972). The incubation time and concentration of membrane protein was adjusted so that the assay was linear with time and less than 50% of the ATP hydrolysed. Non-enzymic degradation of ATP under these conditions was less than 10% of the total phosphate. ATPase activity was expressed as µmol inorganic phosphate liberated min$^{-1}$ (mg protein)$^{-1}$ at 37°C.

RESULTS

The effect of extracellular pH on the growth of M. smegmatis and M. bovis BCG

M. smegmatis grew rapidly in 7H9 broth at pH 7.0 and the maximum specific growth rate observed was approximately 0.28 h$^{-1}$ (Fig. 1). When the initial pH of 7H9 broth was adjusted to pH values in the range 4.5 to 7.0, the growth rate decreased with declining extracellular pH to approximately 0.09 h$^{-1}$ at pH 4.5 (Fig. 1). A comparative analysis with M. bovis BCG under identical growth conditions revealed a similar pattern of pH sensitivity (Fig. 1). In these experiments, the final pH was between 0.2 and 0.5 units higher than the initial pH value.

Regulation of internal pH by M. smegmatis and M. bovis BCG

Oxygen consumption measurements were performed to determine the energy status of washed cell suspensions for internal pH measurements. Non-energized cell suspensions of M. smegmatis at pH 7.0 consumed oxygen at a rate of 86 nmol min$^{-1}$ (mg protein)$^{-1}$ and the addition of glucose increased the rate to 165 nmol min$^{-1}$ (mg protein)$^{-1}$. At pH 5.0, the rate of oxygen consumption by non-energized cells was 99 nmol min$^{-1}$ (mg protein)$^{-1}$ and this was increased to 126 nmol min$^{-1}$ (mg protein)$^{-1}$ by glucose addition. Non-energized cell suspensions of M. bovis BCG at pH 7.0 consumed oxygen at a rate of 32 nmol min$^{-1}$ (mg protein)$^{-1}$ and the addition of glucose increased the rate to 42 nmol min$^{-1}$ (mg protein)$^{-1}$. At pH 5.5, the rate of oxygen consumption by non-energized cells was 21 nmol min$^{-1}$ (mg protein)$^{-1}$ and this was increased to 24 nmol min$^{-1}$ (mg protein)$^{-1}$ by glucose addition.

The use of radioactive probes to measure the total Δp requires corrections for non-specific binding of probes such as TPP$. Since the cell wall of mycobacteria is unlike that of conventional eubacteria, we first tested the effect of ionophores and protonophores on the growth of these bacteria. The following inhibitors at the concentrations listed completely arrested growth of exponentially growing cells of M. smegmatis at pH 7.0: CCCP, 100 µM; DCCD, 200 µM; monensin, 100 µM; nigericin/valinomycin, 10 µM each. At pH 5.0, the following concentrations were required to inhibit growth of M. smegmatis; CCCP, 50 µM; DCCD, 300 µM; monensin, 10 µM; nigericin/valinomycin, 10 µM each. These inhibitors were also effective against M. bovis BCG at similar concentrations (data not shown). These results show that the cell wall of M. smegmatis and M. bovis BCG did not pose a barrier to these compounds.

The effect of extracellular pH on intracellular pH regulation was studied over the pH range 4.0 to 7.0 (Fig. 2). The ΔΨ of M. smegmatis was approximately −178 mV at pH 7.0 and decreased with declining pH (Fig. 2a). As the ΔΨ decreased, the total Δp remained greater than −180 mV and there was an increase in the ZΔpH from −8 mV at pH 7.0 to −155 mV at pH 4.0 (Fig. 2a). These results indicated that M. smegmatis was interconverting ΔΨ to ZΔpH to maintain the Δp constant. The internal pH as a function of the external pH is shown in Fig. 2b. The maximum ΔpH (2.3 units) was observed at pH 4.5. Identical experiments were carried out with M. bovis.

BCG (Fig. 3). As the external pH declined, the $\Delta V$ decreased to approximately $-50 \text{ mV}$ and the $Z\Delta pH$ increased to $-130 \text{ mV}$, but the $\Delta pH$ did not remain constant (Fig. 3a). The internal pH as a function of the external pH is shown in Fig. 3b and the maximal $\Delta pH$ was $2-1 \text{ units}$ observed at an external pH of $4-0$.

**Lethal pH for *M. smegmatis* and *M. bovis* BCG**

Based on the experiments of Foster & Hall (1991), one can estimate the lethal internal pH by adding protonophores, compounds that move protons to equilibrate the internal pH with the external pH, to cells suspended in medium at pH $5-0$, an external pH that is ordinarily not harmful to the cell. Correlations between measured internal pH and viability will indicate the internal pH at which viability declines. When increasing concentrations of CCCP (0–1 mM) were added to *M. smegmatis* cells (OD$_{600}$ 1-0) resuspended in non-supplemented 7H9 medium containing 20 mM glucose at pH $5-0$, the internal pH declined and at 1 mM CCCP the internal pH was $5-1$ (Fig. 4a). The viability of *M. smegmatis* decreased with increasing CCCP concentration and at $500 \mu M$ CCCP there was a 99% reduction in cell viability (Fig. 4b). At an external pH of $7-0$, the addition of $500 \mu M$ CCCP caused only a 20% reduction in cell viability (data not shown) indicating that the decline in cell viability caused by CCCP was a low-pH-induced lethality.

Identical experiments were performed with *M. bovis* BCG, but in these experiments the extracellular pH used was $5-5$. The addition of increasing concentrations of CCCP (0–1 mM) to *M. bovis* BCG cells resuspended in non-supplemented 7H9 medium containing 20 mM...
glucose at pH 5.5 caused the internal pH to decline, and at 1 mM CCCP the internal pH was 5.9 (data not shown). The viability of M. bovis BCG decreased with increasing CCCP concentration and at 1 mM CCCP there was a 90% reduction in cell viability (data not shown). At an external pH of 7.0, the addition of 1 mM CCCP caused only a 15–20% reduction in cell viability (data not shown).

**Effect of protonophores, ionophores and DCCD on intracellular pH regulation in M. smegmatis**

To gain a better understanding of how mycobacteria regulate their internal pH, experiments were performed with M. smegmatis and known inhibitors of key proteins (e.g. proton-translocating F$_{1}$F$_{0}$-ATPase) and the generation of ionic gradients (e.g. H$,^{+}$, K$,^{+}$, Na$,^{+}$) across the cell membrane that have been implicated in pH homeostasis. The addition of either the protonophore CCCP or the ionophore nigericin (K$^{+}$/H$^{+}$ antiporter) in combination with valinomycin (K$^{+}$ uniporter), or monensin alone (Na$^{+}$/H$^{+}$ antiporter) to cells at pH 5.0 almost completely dissipated the ΔpH gradient (Table 1). Valinomycin alone had no effect on the ΔpH gradient. When DCCD (1 mM), an inhibitor of the F$_{1}$F$_{0}$-ATPase, was added to cells at pH 5.0, the internal pH was 5.70 (Table 1). At neutral pH, under all conditions tested, the internal pH was alkaline with respect to the external pH (7.28–7.60) in the presence of the inhibitors used (Table 1).

Growth at low external pH has been shown to induce the synthesis of the F$_{1}$F$_{0}$-ATPase in Enterococcus faecalis (Kobayashi et al., 1984, 1986). To determine if a membrane-bound proton-translocating ATPase was being synthesized in M. smegmatis in response to low external pH, cells were grown at pH 7.0 and pH 5.0, and the amount of ATPase activity determined in purified cell membranes. The cell membranes from cells that were grown at pH 7.0 had $4.63 \pm 0.49 \mu$mol min$^{-1}$ (mg protein)$^{-1}$ ATPase activity. The ATPase activity in cell membranes of cells grown at pH 5.0 was $6.48 \pm 0.43 \mu$mol min$^{-1}$ (mg protein)$^{-1}$. The pH optimum of the ATPase was approximately 7.0 from both pH 5.0 and 7.0 grown cells.

The F$_{1}$F$_{0}$-ATPase has been shown to be essential for the survival of Escherichia coli at external pH values below 4.0 (Pearson et al., 1997). Further experiments were conducted to determine the effect of DCCD on the survival of M. smegmatis at both acidic and neutral pH. M. smegmatis cells were incubated in sodium citrate/phosphate buffer at pH 3.0, 5.0 and 7.0 in the presence

**Table 1. Effect of CCCP, DCCD, monensin and nigericin/valinomycin on the intracellular pH of M. smegmatis**

Internal pH was measured by $^{14}$C]benzoic acid equilibration in cells oxidizing glucose. Glucose was added to achieve a final concentration of 20 mM. All inhibitors were added 15 min prior to the addition of $^{14}$C]benzoic acid. The internal pH values are the means of two independent experiments and the standard error is shown.

and absence of 1 mM DCCD, a concentration shown to lower the internal pH at external pH 5·0 (Table 1). In the absence of DCCD, M. smegmatis survived at each of the pH values tested (Fig. 5). The addition of 1 mM DCCD caused a 60% reduction in viable cell numbers of M. smegmatis at pH 7·0 and a 72% reduction at pH 5·0 (Fig. 5). At an external pH of 3·0, DCCD caused a 99% decrease in cell viability. These results demonstrate that ATPase activity is required for survival of M. smegmatis at all pH values tested, but appears to be more essential for survival at low pH values (e.g. pH 3·0).

DISCUSSION

In this study we have carried out a detailed investigation of how mycobacteria cope with low pH using two model organisms; the fast-growing M. smegmatis and the slow-growing M. bovis BCG. Our findings indicate that the growth of M. smegmatis is inhibited as the external pH decreases below 4·5, thus supporting previous studies (Chapman & Bernard, 1962; Portaels & Pattyn, 1982). M. tuberculosis H37Rv has been reported to have a narrow pH range for growth between 6·2 and 7·3 with marked attenuation observed at pH 5·0 and 8·4 (Chapman & Bernard, 1962). In this study, growth of M. bovis BCG was inhibited at pH values below 5·0. The results reported here demonstrated that both species of mycobacteria adopt intracellular pH homeostasis. M. smegmatis and M. bovis BCG maintained their internal pH in the range 6·1–7·2 when examined over the external pH range of 4·0–7·0. At an external pH of 5·0, the internal pH of these organisms was 6·6–6·7. Zhang et al. (1999) have reported that at an external pH of 5·0, the internal pH of M. tuberculosis H37Ra was close to 7·0, supporting the work in this communication and suggesting that M. tuberculosis adopts pH homeostasis.

The maintenance of intracellular pH near neutrality when faced with decreasing external pH requires changes in the ZΔpH that is a component of the Δp. One mechanism bacteria employ to modify their ZΔpH while maintaining Δp constant is to make compensatory changes in ΔΨ. This may be accomplished by the use of various cation transport systems (Booth, 1985). For example, Enterococcus faecalis and E. coli are able to interconvert ZΔpH for ΔΨ by electrogenic K⁺ transport (Bakker & Mangerich, 1981; Booth, 1985). Results here indicated that M. smegmatis interconverted ΔΨ for ZΔpH to maintain the Δp constant with declining external pH; the Δp values were in good agreement with those published for other respiring neutrophiles (Kashket, 1985). In contrast to M. smegmatis, the Δp for M. bovis BCG varied over the pH range studied. The differences in Δp were largely reflected in the ΔΨ values that varied significantly between the two species. M. tuberculosis has been shown to express a multidrug efflux pump, Mnr, that confers resistance to TPP⁺, ethidium bromide and erythromycin (De Rossi et al., 1998). Importantly, M. smegmatis does not contain the mnr gene and accumulates [²H]TPP⁺ with no efflux (De Rossi et al., 1998). M. bovis has been shown to contain the mnr gene (De Rossi et al., 1998) and therefore we cannot rule out the operation of a TPP⁺ efflux pump in M. bovis BCG; this may explain the low levels of TPP⁺ accumulation (e.g. low ΔΨ) observed in this species and therefore the large fluctuations in the Δp observed with external pH.

Studies with the protonophore CCCP, used to equilibrate internal pH with external pH, indicated that the lethal internal pH for mycobacteria was less than pH 6·0 and this was associated with a rapid decrease in cell survival and viability suggesting that in mycobacteria, acid death is related to internal pH rather than external pH. However, it should be pointed out that at high concentrations of CCCP used, not only may H⁺ be moved but also other ions (e.g. internal K⁺) and therefore the effect on viability may not only be due to acidification of the cytoplasm. Foster & Hall (1991) showed that high concentrations of the protonophore dinitrophenol (200–400 µM) were required to collapse the ΔpH of S. typhimurium. At an external pH of 4·0, non-growing cells of both mycobacteria had a significant Δp (greater than −150 mV) and the internal pH was greater than pH 6·0, but neither species of mycobacteria could grow at this external pH. The reason why these bacteria are unable to grow under conditions where the Δp and internal pH appear to be favourable for growth is unknown. Perhaps the act of maintaining a high internal pH under conditions of low growth rate and ATP generation decreases the amount of energy available for growth. The mycobacteria may stop growing at acidic pH in order to direct energy towards maintenance of their internal pH, which is crucial for their survival.
Alternatively, there may be a pH-sensitive element (e.g., membrane-bound protein) that is essential for the growth of *M. smegmatis* and *M. bovis* BCG at acidic pH.

The basic mechanism(s) that mycobacteria use to cope with acidic pH is not known, but the ΔpH gradient of *M. smegmatis* at pH 5·0 was dissipated by the protonophore CCCP and the ionophores monensin and nigericin (Pressman, 1976), indicating that permeability of the cytoplasmic membrane to protons plays a key role in maintaining internal pH near neutral. Harold et al. (1970) demonstrated that the generation and maintenance of the pH gradient of *Ent. faecalis* was energy dependent, and could be prevented by incubation with the F\(_{1}\)F\(_{0}\)-ATPase inhibitor DCCD. Furthermore, *Ent. faecalis* has been shown to increase the amount of F\(_{1}\)F\(_{0}\)-ATPase twofold when the internal pH is lowered artificially by gramicidin D or growth at low pH (Kobayashi et al., 1984, 1986). The ability of low pH to also increase the amount and activity of proton ATPases has also been reported in other bacteria (Nannen & Hutkins, 1991; Miwa et al., 1997; Amachi et al., 1998; Kullen et al., 1999). In *E. coli* and *Bacillus subtilis*, environmental pH does not influence expression of the ATP operon (Santana et al., 1994; Kasimoglou et al., 1996). In this study, DCCD caused a reduction in the ΔpH of *M. smegmatis* and there was an increase in the level of membrane-bound ATPase activity in cells that were grown at pH 5·0, implying a potential role for this enzyme in intracellular pH homeostasis. Piddington et al. (2000) have demonstrated a role for Mg\(^{2+}\) in the adaptation of *M. tuberculosis* to mildly acidic growth conditions, but the role of Mg\(^{2+}\) was unknown. The authors hypothesized that Mg\(^{2+}\) may play a role in the maintenance of neutral pH, perhaps by influencing the Mg\(^{2+}\)-dependent proton translocating ATP synthase. Inspection of the *M. tuberculosis* genome sequence reveals homologues of ATP synthase genes (e.g., *atpBFEADHCG*) (Cole et al., 1998).

Datta & Benjamin (1997) have demonstrated that DCCD at 1 mM inhibits the survival of *Listeria monocytogenes* at pH 3·0 but had no effect on the survival of *L. monocytogenes* at pH 7·3, indicating that the effect of DCCD was due to low-pH-induced lethality. Our results demonstrated that *M. smegmatis* exhibited a striking sensitivity towards DCCD at acidic pH, suggesting that the ATPase may be more essential for survival at acidic pH. *E. coli* mutants defective in the F\(_{1}\)F\(_{0}\)-ATPase (e.g., *atp::Tn10* or *Δatp*) are extremely acid sensitive, but only to external pH values below 4·0. To test the hypothesis that the ATPase is essential for survival of *M. smegmatis* at low pH values and rule out potential non-specific effects of DCCD, further work is required using *atp* mutants of *M. smegmatis*.

In conclusion, our data demonstrate that both species of mycobacteria studied here adopt intracellular pH homeostasis to maintain their internal pH near neutral at acidic pH. The permeability of the membrane to protons and the activity of the membrane-bound proton F\(_{1}\)F\(_{0}\)-ATPase play important roles in this process. Current studies are aimed at determining the molecular responses of mycobacteria to pH stress.

**ACKNOWLEDGEMENTS**

This work was funded by a New Zealand Lottery Health Grant. We thank Helen Billman-Jacobs and Dr Geoff deLisle for supplying bacterial strains, and John Foster, Fernanda da Silva Tatley and Theresa Wilson for helpful discussions.
